## SYMPOSIUM ON DISEASES OF METABOLISM

THE following clinics are included in this Symposium:

Italo F. Volini: GOUT: A REPORT OF TEN CASES FOR THE YEAR 1935

Rollin T. Woodyatt: THE PREVENTION OF DIABETIC COMA

Clifford J. Barborka: OBESITY

Robert W. Keeton: THE TREATMENT OF MALNUTRITION IN GENERAL PRACTICE

C. A. Aldrich: THE USE OF VITAMINS IN CHILDREN'S DIET

Charles A. Elliott and Walter H. Nadler: INSANITION

## CLINIC OF DR. ITALO F. VOLINI

### COOK COUNTY HOSPITAL

#### GOUT: A REPORT OF TEN CASES FOR THE YEAR 1935

Most contemporary writers when describing gout comment on its rare occurrence. Sir Thomas Clifford Allbutt in the introduction to his article on gout writes, "Although in the earlier days of my practice it was common enough, a typical podagra is now becoming less and less frequent even to rarity." However, a disease incidence of 2 per 100,000 demands more clinical attention. Arthritis clinic statistics in some instances report from 0.5 to 0.7 per cent of cases of gout. For the year 1935, in the Cook County Hospital there were 8 hospital admissions. Hench, in a series of 100 cases of gout, states that only 12 were recognized before admission in spite of the fact that plain clinical evidence was present in the majority of patients.

The following case history dramatically illustrates the serious results of such diagnostic error. M. F., male, age thirty-four, entered the hospital March 12, 1935, with a history of painful swelling and discharging wound of the left big toe. The left big toe became irritated and inflamed two months ago, following which onset alternating irregular periods of improvement and relapses were described. Four days prior to admission a physician incised the angry inflamed area which has been bleeding profusely and discharging considerable purulent material since. Examination revealed a dirty sloughing wound of the medial and upper aspect of the left toe with profuse purulent discharge. Microscopic examination revealed, in addition to the pus cells, the presence of sodium urate crystals in the discharge. The metatarsophalangeal joint was

apparently involved although the uratic crystals in the discharge were derived from adjacent tophi. Tophi were widely distributed, in both ears, in the vicinity of the many small joints of the hands and feet and both olecranon bursae. The blood uric acid was 5.75 mm. per 100 cc. The x-ray report read "The hands and feet reveal the typical bony changes of gout." The previous history dates back ten years with joint inflammation involving the feet, hands, elbows with the development of many small nodules in these locations.

He improved considerably on a purine-free diet and colchicine therapy but was released from the hospital at his own request, fourteen days after admission, with the wound still draining. No follow-up history could be obtained.

This patient attributed the most recent acute episode of his arthritis to traumatism due to excessive walking two months ago. He denied any possible influence of food or alcoholics because of careful adherence to a strict dietary regime he was educated to many years ago.

This illustrates one of the most obscure and least understood phases of gout—the pathogenesis of the acute attack. It cannot be definitely stated as has been generally maintained, that the acute crisis is the result of the sudden deposition of urates into the joints. Unfortunately, chemical analysis of local tissue and fluids in acute attacks show in many instances no deviation from the normal quantitative levels. However, it is clinically recognized that causes of excessive purine intake or of excessive purine production precipitate acute attacks of gout.

Thus the episode follows excessive food intake, especially high nucleoprotein diets, meats which elevate the exogenous purine metabolism level. The endogenous purine metabolism is elevated from the destruction of body cell nucleoprotein. Thus acute attacks are reported to follow radiation therapy, especially in leukemia; following the crisis in pneumonia from the leukocytic disintegration and absorption of the pneumonic exudate, following operations, after profuse diuresis. Naturally, these results are only found in the gouty subject.

approximately 50 per cent of the uric acid production by some method not understood. Most of the remainder is excreted in the urine. Uric acid is highly insoluble, more so in an acid medium, particularly in the presence of appreciable amounts of sodium chloride. It is to be noted here that cartilage possesses probably the highest concentration of any tissue of sodium chloride. Nucleoproteins result from the endogenous destruction of cells within the body and from exogenous sources such as meat and vegetables. Uric acid thus has an endogenous and an exogenous source respectively. In the lactating infant purines are synthesized from purine-free food by the liver most probably. This occurs also in birds, reptiles, and the spawning salmon.

We can now consider the methods by which uric acid can accumulate in the blood and tissues.

First, by an increased production due either to excessive exogenous purine intake or to excessive endogenous source production from the disintegration of cellular nucleoprotein or certain products of muscle metabolism.

Second, by insufficient elimination or excretion by the kidney.

Third, by insufficient destruction of the normally destroyed fraction of the uric acid.

Fourth, by increased synthetic uric acid built up as in the nursing infant from nonpurine sources.

Fifth, by increased affinity of tissues locally for uric acid, possibly due to hypersensitiveness with allergic precipitation. It is to be recorded that the Italian investigators have demonstrated that cartilage possesses the highest fixing power for uric acid of any tissue in the body.

The weight of evidence points to a functional disturbance of the kidney with inability to excrete uric acid. Thannhauser contends that there is always less than 50 mg. uric acid per 100 cc. of urine which is pathognomonic of gout. Case No. 3 in my series, male, age forty-one, was admitted May 25, 1935, with an afebrile polyarthritis. Blood uric acid was 7 mg. per 100 cc. Urinary uric acid on three occasions revealed 9 mg.,

18 mg., and 10 mg. per 100 cc. urine. Normally this figure should be 50 mg. per 100 cc. of urine. In the year 1935, 17 patients are reported with gout: 2 in private practice and 5 at the Cook County Hospital. None of the patients had been seen previously. They were all males, varying from thirty-five to seventy-nine years in age, average forty-nine years. The blood uric was elevated above the normal in 7 varying from 4.9 to 7 mg. Four showed tophi. Two cases showed x-ray changes typical of gout, 4 an x-ray diagnosis of arthritis.

The results of therapy of the acute attacks are usually prompt. Rest and local heat are indicated. A purine-free diet, consisting of milk, egg, fruits, bread, is necessary for three to four weeks. Drug treatment may require opiates in some form when the pain is severe. Colchicine is the remedy of choice in 1-mg. dosage three times daily reduced to twice or once a day after the second day, discontinuing it immediately if the patient has a loose stool, a toxic manifestation. This drug will lose its effect after repeated attacks. Thus, B. M., age sixty-two, Case 10 in my series, having used colchicine for eight years for numerous attacks, always with relief, obtained no result in his most recent episode. He was highly intolerable to cinchophen and neocinchophen, vomiting at the first dose. Immediate cessation of symptoms occurred when given a mixture containing codeine sulphate, potassium iodide, phenacetin and sodium salicylate.

Cinchophen and neocinchophen frequently give immediate improvement acting first as analgesics and secondly directly on the kidney to increase the uric acid output in the urine. While the beneficial action is rapid in gout it is not to be construed that arthritis which responds to cinchophen is gout. Many nongouty arthritics obtain prompt relief from pain from this drug because of its pronounced analgesic activity. Personally I believe it a more effective remedy than colchicine especially as it can be given over longer periods of time than the former alkaloid.

Intermittent and carefully supervised administration of these drugs is necessary because of the danger of resulting

toxic liver atrophy with fatal outcome. Hesitancy however in prescribing cinchophen is not warranted in the florid gouty patient when administration is accompanied by high carbohydrate intake and associated alkalis. Cinchophen is much more effective than neocinchophen and usually 5-grain doses, four to six times in twenty-four hours are adequate, using three- or four-day treatment intervals with a similar duration of no drug administration. My experience indicates quicker and more certain results with combinations of opiates, salicylates, phenacetin, iodides and cinchophen after the preliminary colchicine treatment or where colchicine fails or toxic manifestations follow its use.

Interval treatment demands the absolute interdiction of all forms of alcoholic beverages. The diet can be increased in variety but it must be stressed that overfeeding will produce attacks. Meats, fowl and fish are permitted in restricted amounts, but the rich purine-containing foods such as liver, kidneys, sweetbreads are forbidden. Recent evidence points to the provocative effects of high fat intake on gouty arthritis. A generous carbohydrate fraction with low fat percentage is to be sought for in the dietary calculation.

## CLINIC OF DR. ROLLIN T. WOODYATT

### PRESBYTERIAN HOSPITAL

---

#### THE PREVENTION OF DIABETIC COMA

PRIOR to 1921 relatively few doctors were especially interested in diabetes. The treatment called for a technical knowledge that few possessed, and except in the milder types of cases or in the earlier stages of the more severe types, it was indecisive at best, so that the average doctor had little incentive to master the subject. The discovery of insulin changed this picture.

The past fifteen years have witnessed an educational movement designed to spread throughout the profession a better knowledge of the treatment of diabetes and it has accomplished much. However, so much has been written and said that there is some danger of leaving a confused impression of the relative importance of different things, so that the doctor in more or less general practice might possibly welcome some simplification.

All the things that have been taught about the care of the diabetic patient fall into two groups, the prime essentials and the details of relatively less importance. The former are few, the latter many. I will undertake to bring out some prime essentials.

There is one thing to be known about diabetes that from the practical standpoint is more important than all the rest put together, and that is, *how to keep the diabetic patient alive*; for so long as the patient remains alive any errors in respect of the details of treatment can still be corrected and the patient can be restored to a state of health with or without some irreparable scars; but if he is allowed to die there is

nothing more to be done about that. No matter how carefully all the details may be carried out except those that are essential for the preservation of life, all the benefits of treatment are transitory.

They tell the story of a young Kentucky lawyer who was taking an oral examination for admission to the bar before a judge. The judge asked him a question on constitutional law and he knew nothing about it. Then the judge asked him a question from Blackstone and he admitted that he had never read that book. "Well!" said the judge, "just what *do* you know about the law?" The candidate said, "The statutes of the state of Kentucky, your Honor. I know all there is to know about them." "Well!" said the judge, "That is interesting and also very commendable—but, young man, do you appreciate the precariousness of your situation?" "I am not sure that I understand your Honor." "Why!" said the judge, "Do you not realize that the legislature of the state of Kentucky may now convene at any time in the next few weeks and repeal all those things—and that then you won't know a damn thing about the law?"

There are many patients in that situation. They know all the statutes of grams and calories, carbohydrate, protein, fat, etc. They keep the urine *sugar free*, report for blood sugar determination. Their weight is right and they are in excellent health, but in spite of all that they are still in a precarious situation. Some day they will go away from home and catch a cold or the "flu" or a tonsillitis or an appendicitis, or have a tooth extracted or they will be overcome by the heat or suffer a nervous or emotional strain, and then not knowing what to do they will develop acido-sis and go into coma. An intercurrent infection or whatever it is will repeal all they know about diabetes.

According to Dr. Joslin's statistics diabetic patients live on the average eleven years after the beginning of the diabetes. In many cases the diabetes itself, that is to say, the metabolic disorder that we call diabetes, is not the primary cause of death. It may have nothing to do with the patient's death or

it may be merely a contributing factor. When diabetes itself is the cause of death—and I am still referring to the metabolic disorder as in contradistinction to the underlying disease or *causa morbi*—it operates by causing acidosis which throws the patient into coma, or so lowers his resistance to the intercurrent disease that he dies of that. As a matter of fact, most young diabetics die in these ways. So acidosis alone or in combination with other diseases determines the death of many patients and has much to do with the eleven-year average tenure of life. Still the death of a patient in acid coma or as a result of an uncontrolled acidosis working in conjunction with an intercurrent disease is an accident, an accident in the literal sense of the word as applied to an automobile collision, and it is a very largely preventable accident too. No diabetic need die in coma or from the effects of an acidosis working in conjunction with other diseases. Knowledge available at the present time is sufficient for the prevention of all such deaths. Now in a series of paragraphs I will state some items of knowledge which when acquired and applied by diabetic patients have been sufficient to prevent death in acidosis.

In teaching patients what they must know in order to prevent and check acidosis, it is important to remember that they must know these things better than merely as intellectual conceptions. It is not enough that these things be explained to the patient so that he intellectually understands them. Nor is it enough that he have them inscribed on papers at home. As Foch said concerning the principles of war, "They must be ingrained as it were in the very bones so that the officer acts in accordance with them automatically, without thought." So in the case of the diabetic certain items of knowledge must be instilled to such a depth that the patient will act in accordance with them reflexly. We must establish a conditioned reflex.

The first thing to know is *when to anticipate acidosis, when to be on the lookout for it*. The next thing to know is *how to detect it in the early stages*. The third thing to know is *how to stop it*.

*When the diabetic patient has a cold he must know that that cold may or may not bring on acidosis.* The important point is the realization. If he does not realize he will not act. If he does he will be very apt to act. When the diabetic patient has a "cold" he should:

1. Examine the urine at frequent intervals. He should examine the urine *four times a day, at meal hours and bedtime.*

2. When sugar is present, he should test for *acid.*

3. When both sugar and acid are found in the urine, he should go on a suitable *Emergency Program.*

*What applies to a cold* applies in general to any intercurrent infection, any major or minor operation, a tooth extraction, a vaccination, a nervous shock, an emotional upset, and above everything else, an *omission of insulin.* A cold or anything as bad as or worse than a cold, indeed any interruption of the even tenor of the patient's health should be considered as a good reason for testing the urine four times a day, at meal hours and bedtime.

**Concerning the Ferric Chloride Test.**—The simplest way to make the test is to take 5 cc. of urine in a test tube and add 2 cc. of 10 per cent aqueous ferric chloride solution all at once. Then if the test tube is shaken there will seldom be any precipitate of the phosphate of iron to cloud the urine. The precipitate which appears when small quantities of ferric chloride solution are added to the urine can be redissolved in an excess of the reagent. *Five cc. of urine with 2 cc. of 10 per cent aqueous ferric chloride* will usually be free of precipitate and not unnecessarily diluted.

The presence of aceto-acetic acid in the urine means that the body is losing alkali. A patient who is showing aceto-acetic acid in the urine also has a greater quantity of beta-hydroxybutyric acid in the urine. These two acids entering the body from endogenous sources are being neutralized by free alkali in the body and are being excreted in the form of salts, thus carrying away a part of the base that formerly existed in the form of free alkali in the body. *The alkali*

reserve is being depleted. Continued depletion will lead to coma. Aceto-acetic acid in the urine means alkali bleeding. Know when to be on the lookout for it. Look for it. Find it, and immediately stop it. How shall we do this?

(A) In the early stages, before the ketosis has resulted in enough depletion of the alkali reserve to cause clinical symptoms (symptoms of acid intoxication), the following procedure has proved effective in practice with hundreds of

The diagram shows a circle representing a twenty-four-hour day divided into four quarters of six hours each. At the beginning of each period the patient does the four things in the inner circle. The diagram assists in his education.

patients during a period of fifteen years. Other procedures may be as good. I know the soundness of this.

**Emergency Program.**—Divide the twenty-four hours into four periods of six hours each. At the beginning of each period

1. Empty the bladder.
2. Test the urine for sugar and acid.
3. Give a dose of insulin.
4. Give a standard feeding.

A *standard feeding* consists of 400 cc. (2 glasses) of milk or 300 cc. of orange juice.

*The first insulin dose:* One quarter of the patient's regular dose for twenty-four hours plus 5 units.

*The second dose:* Five units more than the first if acid is still present.

*Following doses:* Increase the dose by 5 units each period until acid is absent.

*Later:* Adjust the dose from period to period as requisite to control the glycosuria and insulin reactions.

*Note:* In the event that the patient is on protamine insulin, leave the protamine insulin dosage alone, that is to say as it has been before, and superimpose the emergency program on it.

**(B) With Early Symptoms of Acid Intoxication.**—The program may be the same as (A) (for ketosis without any toxic symptoms) with the following exceptions:

1. When there are symptoms of beginning intoxication *omit the feedings until the symptoms are gone.*

2. Make the *first dose of insulin decisive*, so that the symptoms will disappear within the first six hours. With early symptoms a decisive dose may be  $\frac{1}{2}$  to 1 unit per kilo of body weight. *Do not be afraid of insulin reactions in the presence of symptoms. Be afraid of coma.*

When the symptoms are stopped, insulin reactions can easily be prevented by hourly feedings of 50 to 100 grams of orange juice, or more if required. The hourly feedings should be enough to maintain some glycosuria. So long as sugar is passing through the kidneys into the urine there is no danger of insulin reaction. Patients sometimes gain the impression that insulin reactions and glycosuria may occur together. This is not true. The patient may pass sugar-containing urine into the bladder in one hour and sugar-free urine the following hour. In the second hour he may have an insulin reaction. Urine voided at this time may contain sugar, but this sugar was secreted the hour before and has lain in the bladder. Unless the bladder has been emptied sugar secreted

prior to the occurrence of the insulin reaction may still be present at the time when the insulin reaction occurs.

As soon as the symptoms of acid intoxication have been considered, the case becomes one of ketosis without any clinical symptoms and treatment proceeds as under (A).

If all patients and doctors were on the lookout for acidosis and if they discovered it in the early stages and would carry out some such simple procedure, acidosis would seldom progress to the point of producing any clinical symptoms at all. However, too often it goes undiscovered and symptoms appear. Even then as a rule there is plenty of time to stop the affair without serious trouble if the early symptoms are recognized. Therefore, in the education of a patient it is important to inculcate a definite knowledge of

*The early symptoms of Acid Intoxication:*

1. *Weakness* where none has existed before, or accentuation of a previously existing weakness.
2. *Anorexia or nausea or nausea and vomiting.*
3. *Inclination to rest or sleep by day.*
4. *Increased rate of respiration* that may be present at rest or only after a mild exertion.
5. *Retardation of the mental reactions.*
6. *Facial flush.*
7. *Acetone odor on the breath.*

*If a diabetic patient has any one or more of these seven symptoms he should examine the urine for sugar and acid. Unusual fatigue or anorexia or nausea in a diabetic should be considered as evidence of acidosis until tests have shown that none exists.*

With the development of more severe symptoms of acid intoxication, the condition of the patient is usually such that he is incapable of doing anything about it. We have been discussing especially the *prevention* of coma. With more than mild or early symptoms the time for prevention has already passed and we must speak of the treatment of the precomatose patient. However, the management may still be conducted by six hourly periods. I will not undertake to discuss

in detail all phases of the treatment of the precomatose case, but I will undertake to state some steps that may well be taken in the first six hours.

(C) **First Period Management of the Precomatose Case.**—In the first period the following steps may be taken:

1. *Give a maximum dose of insulin.*

Establish at once as much insulin action as can be produced by any dose. In critical cases repeat the original maximum dose in the middle of the period, three hours after the original dose. Two units per kilo of body weight will probably produce as much effect as a larger dose. Having giving the initial maximum dose, give

2. *A cleansing enema*, to be followed by

3. *A retention enema* of normal salt solution which may have a volume of 6 cc. per kilo of body weight. In these cases the bowel is an invaluable vehicle for the administration of water. Do not dilate it by undertaking to give too much fluid by bowel at any one time, and do not irritate it by introducing sugar, bicarbonate, or any other foreign substance. Experience has shown that 6 cc. of warm normal salt solution per kilo of body weight will usually be retained when given by bowel each six hours for a number of periods. Attempts to give more very often result in the retention of less in twenty-four hours.

4. *Aspirate the stomach contents* in order to remove any acid that may have accumulated and to detect dilatation or atony of the stomach if this be present.

5. Conditions permitting, *give water by mouth* at the rate of 100 cc. per hour per 70 kilos of body weight ( $1\frac{1}{2}$  cc. per kilo of body weight). If there is any doubt as to the ability of the stomach to move this quantity of water through the pylorus, aspirate again in three or four hours to be sure that the water is passing through. If it is not moving through do not continue for fear of dilating an atonic organ. Let the stomach rest for a while and try again later.

If 3 and 5 are successfully carried out, the total water administered for the six-hour period will amount to 1000 cc.

in the case of a patient weighing 70 kilos (14 to 15 cc. per kilo). This rate of water supply continued for two or three periods will usually suffice to overcome symptoms of dehydration. If this can be done by the alimentary route, there is no need for parenteral administration.

With an incompetent stomach, colon or both, the same quantity of water may be given per period, but in this case it will be necessary to administer the water by a parenteral route. For this purpose normal salt solution by the continuous subcutaneous drip is very effective. If 1000 cc. of water are to be given in the six-hour period by the parenteral route alone, the average rate of administration is 170 cc. per hour. If the bowel will carry 400 cc. and the stomach none, 600 cc. will remain to be given by the parenteral route and so on. There is rarely if ever any need for intravenous injection of any kind. I very seldom go into the vein for any purpose in the treatment of the acidotic case.

In the first six hours of the treatment of a deeply toxic case, it is virtually impossible to overcome the acidosis and hyperglycemia to such an extent that there need be any thought of an insulin reaction or the necessity of administering any sugar. In subsequent periods the need may arise but not in the first. When it does arise, as shown by a failing glycosuria, enough sugar should be given every hour to keep some passing into the urine. By that time it can often be given by mouth. In any event it can always be given by the subcutaneous drip in the form of 10 per cent glucose solution, until the patient is entirely out of danger. Do not let the fear of an insulin reaction cause an unwise cut of the usual dosage. Keep up a plentiful insulin dosage and maintain a moderate glycosuria by hourly sugar administrations. Five to 10 Gm. an hour will usually do, even with excessive insulin dosage. If it can be given by mouth, as 50 to 100 Gm. of orange juice per hour or any equivalent, so much the simpler. If not, it can always be given as 10 per cent glucose under the skin at the rate of 50 to 100 cc. per hour.

The value of the knowledge discussed above can be illustrated by citing the following case.

A man, twenty-eight years old, had been a diabetic since the age of twenty-four. For three years he had been living on a measured diet and insulin. In these years he had remained in excellent condition under the care of a skilful doctor. This patient was well trained in all matters pertaining to quantitative dietetics, administration of insulin, examination of his urine for sugar, etc. He reported to his doctor at frequent intervals for blood sugar examinations and kept a careful diary of his condition. He had no serious difficulties until on a certain occasion he came to Chicago on a business trip.

The weather at this time was exceedingly hot. He was involved in a nervous and emotional strain. On Saturday evening he felt excessively tired. On awakening Sunday morning he was weak and nauseated. Because of the nausea he ate no breakfast and because he ate no breakfast he was afraid to take insulin for fear he might have an insulin reaction, so he omitted his usual morning dose. All day Sunday he felt weak and nauseated. He ate no food and took no insulin.

I saw him in his hotel on Monday morning. He was lying in bed flushed, dry, excessively thirsty, breathing deeply and with difficulty, in typical air hunger. He was given at once a maximum dose of insulin and taken to the hospital, and eventually recovered but only as a result of strenuous treatment.

This patient had not been taught that such a thing as a nervous or mental strain especially with the weather as hot as it was, might be calculated to bring on acidosis. He had the equivalent of a cold but did not "realize" what a cold might do. He had no ferric chloride solution. In fact, he had not been taught to make a ferric chloride test. He had not been taught the early symptoms of acid intoxication. He did not know that the excessive fatigue that he felt Saturday night was highly suggestive. He did not know that in a diabetic patient the occurrence of nausea should be regarded as

evidence of acid intoxication until it has been proved to be due to something else. He did not know that under any conditions and especially under the conditions that existed Sunday morning an omission of a dose of insulin would probably throw him into coma. In other words, this patient had been thoroughly trained in many of the technical aspects of treatment but he had not been trained in the prime essentials, and he came perilously close to death in coma.

## CLINIC OF DR. CLIFFORD J. BARBOCKA

DEPARTMENT OF MEDICINE, NORTHWESTERN UNIVERSITY  
MEDICAL SCHOOL AND PASSAVANT MEMORIAL HOSPITAL

### OBESITY

DISORDERS of metabolism frequently are encountered in medical practice. One of the commonest disorders of metabolism is obesity. Failure on the part of physicians to understand the proper management of obesity or to be sympathetic and interested in directing reducing measures for the patient seeking their counsel, results all too frequently in the overweight seeking relief by quack remedies which in all too many instances lead to definite harm to body tissue and the patient's health.

All too often the intelligent patient receives the reaction of ridicule and is impressed with the idea to leave well enough alone when he seeks medical advice. I feel confident that the reason for the various quack advice and remedies for obesity with all the ridiculous measures and diets that are undoubtedly unsound and harmful can be traced to the failure of the medical profession to give the subject its proper consideration. The laity should be taught that one of the important phases of preventive medicine is the fact that to be overweight beyond a certain limit may be the sign of some serious metabolic disturbance and relief will be sought early.

With the changes in the mode of living that characterize present-day urban existence, a considerable proportion of the adult population indulges in comparatively little muscular activity. Eating habits developed during adolescence, when the demands of physical activity necessitate a large food intake may be continued after the need for a high energy intake has

ceased. It is hard for most people to believe how a small quantity of food can influence weight. An intake of 100 calories a day above the energy expenditure means an increase in weight of about 10 pounds in a year. Reducing by increased exercise is not an easy matter, frequently is ineffective, and in some cases may even be injurious. Those who wish to get rid of accumulated body fat must eat fewer calories than they expend in activity.

### DIAGNOSIS OF OBESITY

The diagnosis of obesity usually presents very little difficulty. The physical appearance of the individual is sufficient ordinarily to make the diagnosis simple, even for the layman. Obesity does not develop rapidly in the average individual and is usually well advanced before the patient seeks medical advice.

One must, of course, differentiate:

**Myxedema**, although usually the patient has associated symptoms of hypothyroidism such as a dry skin, dry and brittle hair, mental retardation, typical facial appearance, intolerance to cold and, of course, the laboratory evidence characteristic of the disease.

**Edema**.—Occasionally widespread involvement of anasarca or ascites may superficially resemble obesity; however, careful physical examination will usually render the diagnosis a simple one.

**Avitaminosis**.—In times of financial depression, such as we have recently had, and in certain long-standing cases of poor food habits, foolish and inadequate diets to reduce an obesity there is apt to be a vitamin and mineral deficiency and these patients may develop a certain amount of subcutaneous edema and a puffy appearance of their skin simulating obesity. A careful food history and the rapid disappearance of the apparent obesity occurs on a diet that is adequate in vitamins and calories.

With these few facts differentiated and eliminated it is important, both from the standpoint of completeness of diag-

nosis and as a guide to correct therapy, to make an effort to classify the patient as to his type of obesity.

### DISCUSSION OF OBESITY

The apparent paradox that certain persons get fat and others do not on what appears to be equivalent diets invites much speculation. The old classification of exogenous obesity attributed to inactivity and overfeeding, and endogenous obesity, or the constitutional type, for which a variety of physiologic and pathologic functions has been ascribed, is subject to attack on the basis of Newburgh's contention of obesity, namely, that the subject takes in more than is used up regardless of any disease or any inherited tendency which may be present.

There can be no doubt that obesity is often the result of overindulgence in food and lack of exercise. There are persons, however, who gain weight on what appears to be a moderate intake of food, or even a restricted intake, and who indulge in considerable exercise. In many instances there seems to be an hereditary background as though there was a constitutional tendency to obesity. Many common factors may be observed in the accumulation of evidence of the incidence of the development of obesity. In many cases obesity develops following lactation because of the fact that the young mother in her zeal to supply adequate nourishment for her baby overeats and pushes fluids to a maximum. It is common for obesity to follow convalescence from an operation or from prolonged illness. There are natural periods of alterations of flesh which tend to occur at certain physiologic epochs, as puberty, menses, pregnancy, and menopause.

The problem of obesity in its many aspects has been receiving more attention in recent years and is becoming a significant factor in clinical practice. One of the chief reasons that bring most obese women to the physician is the lack of grace and beauty of figure which, in turn, is likely to bring about certain psychic effects. As a matter of fact, the final impetus that brings the obese person to the physician is one of the sequelae

of obesity rather than the esthetic considerations. Certainly it is the adverse effect on longevity and the predisposition to secondary pathologic changes that should concern the physician. The medical actuarial tables on mortality statistics quickly point out the effects of obesity on the duration of life. The per cent ratio of actual to expectant death of overweight men and women increases proportionally to each 10 pounds of overweight. This fact is recognized by insurance companies, who regard obesity as a serious impairment, and the obese person who desires life insurance has his rate increased considerably because of the extra risk associated. Not alone does the obese individual have a physical and economic handicap, but the abnormal adiposity predisposes to other pathologic conditions. Joslin has emphasized the relation of obesity to diabetes. He found that 70 to 85 per cent of persons with diabetes gave a history of obesity. If there is a latent tendency to diabetes the development of obesity certainly seems to precipitate glycosuria. It is surprising how often the history of obesity is present at the onset of glycosuria. Furthermore, the carbohydrate metabolism seems to be altered, as 40 to 60 per cent of all obese persons have an abnormal glucose tolerance. Foster stated that 50 per cent of patients with hypertension are obese. A large proportion of patients with cholelithiasis are overweight. The development of cardiac embarrassment is likewise a common observation. There also are many minor difficulties, such as varicosities, excessive perspiration and eczema, that arise from obesity. The surgeon is well aware of the poor surgical risk and the possibility of postoperative hernia and the tendency to pneumonia. Many orthopedic problems are aggravated or precipitated by overweight. It has long been known that a certain relation exists between obesity and complete or partial sterility. Some authorities feel that obesity is an exciting cause of sterility although other facts suggest that sterility is primary and that obesity supervenes as a result of metabolic disturbances produced by the elimination of the reproductive functions.

From this brief review it is apparent that obesity, regard-

less of the mechanism by which it may be produced. From a simple gain of 10 to 20 per cent above the normal weight for a certain height, sex, and age, up to veritable monstrosity, should be considered pathologic.

Various endocrine dysfunctions are accompanied often by different types of adiposity and certain regional distributions and peculiar configurations.

Many enthusiasts have suggested that all cases of obesity are due to some fault of the endocrine system. The foreign investigators particularly have emphasized this etiological factor. It requires considerable study and observation to classify definitely any case of obesity and the tendency to attribute all adiposity to endocrinopathy must continually be guarded against.

There can be no question that there are certain cases of obesity which have been definitely linked with endocrinopathies such as pituitary syndromes of adiposis dolorosa, Fröhlich's syndrome, pituitary basophilism, the generalized adiposity of certain cases of hypothyroidism, the eunuchoid type of obesity, and the obesity of hyperadrenalism.

Many other cases of obesity may be of endocrine origin, but there is no justification in classifying them as such unless there is some definite proof of faulty function of some of the glands of internal secretion available. In other words the tendency should be to suspect each case of obesity as not due to faults of glands of internal secretion until you have ruled out the more common causes of adiposity.

The endocrinopathies which have been associated with obesity are:

**Thyroid hypofunction** may possibly cause increased storage of fat by decreasing the basal metabolic rate and thus allow insufficient output of energy to balance the increase in calories. On the other hand, one should not forget that many cases of hypothyroidism are below the average weight. As a matter of fact, in observing the studies of the basal metabolism associated with obesity it is surprising to note how few cases actually have hypothyroidism.

Evans and Strang were the first to emphasize the importance of the correct method of calculating the basal metabolic rate in obese patients; stating that the weight used should be the ideal or expected weight rather than the actual weight. As a matter of fact, in order to justify the diagnosis of hypothyroidism in the presence of obesity the basal metabolic rate must be below normal when the calculation is made according to the ideal weight, rather than the actual weight of the patient, or the patient must present definite clinical symptoms of myxedema.

**Pituitary dysfunction** has been thought for many years to be the cause of certain types of obesity such as dystrophia adiposogenitalis, adiposis dolorosa (Dercum's disease), the adiposity of pituitary basophilism (Cushing's disease) and others. The work of certain investigators suggests that these conditions might not be due so much to the disturbance of the pituitary itself but possibly to the irritation of the underlying brain structure. Evans' work, in which hypophysectomies without injury to the underlying brain tissue is regularly followed by perfect dwarfism without any trace of adiposity, is exceedingly interesting.

The work of Anselmino and Hoffman indicates that there may be a hormone elaborated by the anterior lobe of the pituitary that has something to do with fat metabolism.

**Adrenals.**—It is thought by some investigators that a hormone from the adrenal cortex fixes the blood fats of the tissues. If the adrenal produces obesity, it does it by just the opposite mechanism to that of the thyroid. In other words, hypofunction of the adrenals causes weakness and decreased nutrition; while in hyperadrenalism there is every evidence of exaggerated metabolism. Koster and his associates recently have removed the suprarenal glands with relief of the obesity.

**Gonads.**—Hypofunction of the ovaries has been recognized for many years as one of the most important endocrine causes of obesity. The majority of cases of ovarian failure show an increased tendency to gain weight. This is particularly true of cases of obesity occurring before the menopause. The fre-

quent tendency for obesity to develop in patients where there is ovarian unrest such as puberty, postnuptial sterility, lactation, and the menopause seem to indicate that the ovaries play an important role. Castration or testicular failure in the male causes a definite excess of adiposity.

Two or three other facts should be mentioned in discussing the question of obesity:

**Central Nervous Lesion.**—Weir Mitchell in 1880 suggested what he called a "fat center," which is located in the posterior part of the medulla. This so-called "theory" or "central theory" has been revived by Bernhardt in Germany and Wilder in this country. Wilder suggests that the center is one of the visceral nuclei of the tuber cinereum and the walls of the fourth ventricle. The mechanism as to how this is accomplished is of course problematical, although Wilder feels it is indirectly through the control of the appetite.

**Defective water and salt metabolism** leads to overweight but this is not a true obesity.

### TREATMENT OF OBESITY

In actual practice it is quite difficult to know where exogenous obesity ends and endogenous begins, and in treating the two types of cases very little difference is found in their reaction to the dietary regimes.

The important factors in the dietary treatment of overweight and obesity are:

1. Low calorie content.
2. Adequate protein.
3. Moderately low carbohydrate content.
4. Very low fat content.
5. Sufficient bulk to satisfy hunger.

The important factors in the dietary treatment outlined above need some further discussion.

**Low Calorie Content.**—The caloric intake of the individual at hand is the first thing to be considered and, of course, it must be below the energy requirement of the patient. The calories should be high enough to meet the basic needs of

the body and teach good food habits. One should choose a caloric intake of from 800 to 1,400 calories per day, dependent upon the amount of overweight, the rate at which one desires to reduce, the expected or ideal weight desired, and whether there are any associated problems or complications. Too low a caloric intake is not a good procedure to follow routinely as it does not allow for good food habits and adequate intake of vitamins and minerals. It has poor satiety value and may cause too rapid a reduction of weight with too rapid changes in the tone of the tissues.

**Adequate Protein.**—The protein intake must be adequate to maintain nitrogen equilibrium. This may be covered by using 1 Gm. of protein per kilogram of expected or ideal weight. In addition to the protection of nitrogen balance one should choose proteins of high biologic values, so as to insure the necessary amount of all the amino-acids that aid in the building of the body's tissues. Such proteins are meat, eggs, milk and cheese.

**Moderately Low Carbohydrate Content.**—The carbohydrate content of the reduction diet must be quite limited if much weight is to be lost, yet high enough to maintain nitrogen equilibrium. Strang, McClugage and Evans report that 0.6 Gm. of carbohydrate for every gram of protein used is necessary in a reducing regimen to maintain nitrogen balance. Carbohydrate acts as a protein sparer by protecting the anti-ketogenic fraction of the protein molecule from being transformed into available glucose. In our plan of a reduction diet we use 0.85 Gm. of carbohydrate for each gram of protein used in the diet. This amount is safely above the minimum requirement to preserve nitrogen balance and insures an acid-base equilibrium, avoiding the dehydration effects of acidosis or the hydrophilic tendency of the tissues with alkalosis.

**Very Low Fat Content.**—Fat is the one foodstuff that must of necessity be very low in amount because of the number of calories allowed in a reduction diet and the high caloric value of the fat as compared to the carbohydrate and protein. The purpose of the diet is to give very little fat by mouth in

order that the body may use up its own fatty tissues to make up the deficient caloric intake of energy requirements.

**Sufficient Bulk to Satisfy Hunger.**—The satiety value of the diet is very important. The diet should be planned so that the individual should not be hungry and at the same time should be able to carry on his normal activity. Liberal quantities of green vegetables are given so as to supply sufficient bulk and roughage to aid in bowel elimination and to satisfy hunger. Meat is one of the foods that has a particularly high satiety value. The use of a small amount of fruits at the end of a meal aids a great deal in giving a sense of fulness and satisfaction. Clear meat broths (without fat) are also an aid and have no food value.

By following such a program one will insure a normal metabolizing mixture regardless of the calories given by mouth. In addition, the patients will not ordinarily experience any clinical discomfort, after the first few days, and will tend to lose weight uniformly. It is best to reduce weight gradually by prolonging the period of dieting. This is of advantage in that it accustoms the patient to a small amount of food, so that he is not likely to overeat after the weight has been sufficiently reduced. Also slow reduction lessens the chances of weakening the patient.

#### DIRECTIONS FOR APPLICATION OF DIETS

For reduction of overweight of only a few pounds one can ordinarily attain the desired weight by restricting the obvious fats and the more concentrated carbohydrates of the diet. This may be done by following the typical foods allowed and curtailing those to avoid.

## SIMPLE QUALITATIVE RESTRICTION

Typical foods allowed in reduction diets:

Milk, skimmed and buttermilk.

Egg.

Meat, lean.

Meats low in fat, as:

Chicken—lean portion.

Liver.

Fish, other than salmon.

Shrimp.

Crab meat.

Fruit, 5 and 10 per cent.

Vegetables, 3 and 6 per cent.

Clear soup.

Typical foods to avoid in reduction diets:

Sugar and all sweets.

*Starches as:*

Bread.

Cereals.

Macaroni.

Spaghetti.

Pastry, pie, cakes.

Sweet desserts.

Vegetables high in carbohydrates as:

Potato.

Shelled peas.

Shelled beans.

Corn.

Parsnips.

*Fats as:*

Butter.

Salad oils.

Cream.

Meats high in fat as

Pork.

Lamb chop with large amounts of fat

For the cases of obesity needing greater dietary restriction we have presented three series of reduction diets, calculated by

applying the important factors outlined above, on the basis of an expected or ideal weight of 160 pounds, with varying caloric values from 800 to 1200 calories per day. Diets as low as 800 calories are arranged with adequate vitamins, minerals and salts.

The ideal weight of an individual is determined usually by consulting tables of actuarial standards, choosing the weight on the basis of height, age and sex. It must be remembered that most of the tables of actuarial standards for ideal weight and height are prepared for insurance companies. These tables should serve as an approximate guide and should not be followed exactly. One must take into consideration each individual and use as a goal the best expected or ideal weight for his particular needs, both mental and physical.

Regardless of what the ideal weight should be, the first reduction diet chosen should seldom be more than 20 to 40 pounds below the present weight of the individual, depending on the type and degree of obesity and the patient's tolerance of the loss of weight. For example, a patient weighing approximately 200 pounds should use one of the diets outlined on the basis of an expected weight of 160 pounds.

When a reduction of 10 to 40 pounds has been obtained it is well to add enough food to any diet used so as to maintain the new weight for a period of two to four months. This will allow the body to readjust its metabolism for this newly attained weight prior to further reduction if necessary. The only exceptions to this rule are the cases in which obesity for certain definite reasons requires very rapid reduction, or cases of extreme obesity in which the individual weighs from 280 to 350 pounds.

During this reduction regime one should weigh only once a week, but on the same scales, at the same time of day and before the meal. The approximate average mineral content of the reduction diets outlined are:

<i>Calcium</i>	<i>Phosphorus</i>	<i>Iron</i>
0.783	1.188	0.0134

# REDUCTION DIET FOR EXPECTED OR IDEAL WEIGHT OF 160 POUNDS

(800 Calories)

## QUANTITATIVE AND ESTIMATED QUANTITATIVE TOTAL FOOD ALLOWANCE FOR ONE DAY

(Carbohydrate, 61; protein, 73; fat, 30; calories, 802)

## A FEW SUGGESTED SUBSTITUTIONS FOR REDUCTION DIET

In the place of 10 Gm.  $\frac{1}{2}$  thin slice of bread, may have one of the following:

Skim milk.....	100 Gm....	1 glass
Vegetable, 6 per cent.....	100 Gm....	1 serving
Vegetable, 3 per cent.....	300 Gm....	2 servings
Fruit, 5 per cent.....	100 Gm....	1 serving
Fruit, 10 per cent.....	50 Gm....	1 serving

In the place of 10 Gm. butter, 1 square, may have one of the following:

Salad dressing with oil.....	10 Gm....	2 teaspoons
Cream, 20 per cent.....	15 Gm....	1 tablespoon

In the place of 60 Gm. of meat, 2 ounces, and 15 Gm. of cream, 1 tablespoonful, may have one of the following:

Egg.....	2	
Cheese, solid.....	40 Gm	2 1-inch cubes

In the place of 100 Gm., 10 per cent fruit, 1 serving, may have one of the following:

Fruit, 5 per cent.....	200 Gm....	2 servings
Vegetables, 6 per cent.....	150 Gm....	2 small servings
Vegetables, 3 per cent.....	300 Gm....	3 servings

## ACCESSORY FACTORS IN TREATMENT OF OBESITY

**Exercise.**—The amount of exercise should be increased, unless obesity is complicated by disease, in which exercise is contraindicated.

**Water Allowance.**—Water may be taken as is the habit of the individual. There is no reason to restrict water greatly unless the obesity is complicated by a disease in which limitation of water may be desirable.

**Thyroid Medication.**—Physicians cannot be too strongly cautioned against promiscuous and indiscriminate use of thyroid gland in the treatment of obesity, especially by the laity. The use of thyroid extract outside of the well-controlled advice of a physician is pernicious as it frequently leads to material cardiac injury when taken for long periods or in too large doses. If the physician can observe patients daily and can make frequent tests of basal metabolism it aids materially in reducing the weight rapidly, and under certain conditions may be safely employed.

**Dinitrophenol.**—The introduction of alpha-dinitrophenol into therapeutics by Tainter, Cutting and their collaborators has aroused much interest. The outstanding actions of the drug are sustained increases in metabolism and body temperature with enormous activity of all metabolic functions.

Dinitrophenol is a very treacherous drug, and, at least for the present, should be used only as an experimental therapeutic measure in carefully selected patients under the close supervision of physicians who are familiar with the possible unfavorable reactions.

The original investigators feel that a daily oral dose of from 3 to 5 mg. per kilogram body weight is a safe therapeutic dosage. However, certain human beings have a variable and unpredictable susceptibility to its toxic effects. Its indiscriminate use by the public has already lead to fatalities. Physicians who administer the drug should inform the patient concerning the dangerous symptoms such as: increased temperature, severe urticaria and pruritus; and advise immediate discontinuance of the drug with any suspicious symptoms.

### CONCLUSIONS

The problem of obesity is difficult to solve perhaps because, as DuBois has stated, there is no stranger phenomenon than the maintenance of a constant body weight under marked variation in bodily activity and consumption of food. Few scientific data are available to explain maintenance of normal weight. Many factors, such as disturbance of endocrine glands, water metabolism, specific dynamic action, and fluctuations in basal metabolism, have been held responsible. Such data as Newburgh has recently presented in determining the total heat elimination and total water exchange, with accurate studies of the nature of obesity, do not lend support to the conception of a mysterious economy practiced by the tissues infiltrated with fat.

Obesity can and does occur in patients without showing clinically any direct relation to intake of food. Whatever the mechanism of obesity may be, the clinical fact remains ap-

parent that 2 persons on the same intake may vary in response, one getting fat and another remaining thin. My experience has led me to believe that underweight in the otherwise healthy person also occurs even when the intake of calories is more than sufficient to supply the demands of energy. The so-called "constitutionally" obese person and the healthy person who is underweight may present extremes of the same problem.

The difference between the so-called "exogenous" and "endogenous" types of obesity is only one of degree, not of kind, and both are the result of disordered metabolism which, in the last analysis, is probably due to some glandular dysfunction which alters the previous relation between intake of food and expenditure of energy.

## CLINIC OF DR. ROBERT W. KEETON

RESEARCH AND EDUCATIONAL HOSPITAL AND DEPARTMENT OF  
MEDICINE OF THE UNIVERSITY OF ILLINOIS

### THE TREATMENT OF MALNUTRITION IN GENERAL PRACTICE

The order of the discussion:

- Changes in Weight.
- Nondestructive Weight Loss.
- Acute Destructive Weight Loss.
- Chronic Destructive Weight Loss.
- Vitamin B<sub>1</sub> and B<sub>2</sub> Deficiency.
- Vitamin B<sub>1</sub> Deficiency.
- Vitamin C Deficiency.
- General Considerations.

It is the purpose of this clinic to illustrate the importance of the application of the known laws of nutrition to the treatment of the sick. In the past the appetite has been considered a satisfactory guide for the individual to follow in the choice of food. Indeed there are many doctors who still adhere to this viewpoint. They point to the animals who go about the selection of their food under its dictates and they emphasize the animal's apparent freedom from disease. The dog feels badly and on one occasion refuses his food, on another he may be observed on the lawn eating grass. They say that the patient should be given equal privileges. In viewing such an analogy it should be remembered that the animal continues to live because he can find in his environment all the requirements for life. When one of these requirements ceases to exist, nature exacts her penalty and the species becomes extinct.

In the second place animals have had no opportunities to have their appetites perverted by false prophets. Even under the dictates of such a normal appetite the span of life of the animals is as a rule shorter than that of man. The futility of this viewpoint has become so evident that all of the great state universities have developed departments of animal husbandry.

If we apply this principle that the inborn instinct and appetite is an adequate guide in matters of nutrition to man, then the baby who has had no opportunity to have his appetite spoiled should best be able to select his food correctly. On the contrary every one now recognizes that one of the great triumphs of medicine has been the accurately controlled infant feeding as practiced by our present-day pediatricians.

The study of nutrition is just another chore that advancing medicine has placed on the shoulders of the already overburdened practitioner, but let us face the issue for the study of the subject will yield large rewards in the treatment of patients.

### CHANGES IN WEIGHT

The lay public is quite familiar with the grave significance that is to be attached to a sudden change in weight. If there has been a sharp weight loss, they seek the doctor. If they have gained weight they may take a more philosophical view and regard it as a sign of advancing years. They have been educated to this viewpoint by the refusal of life insurance companies to accept as risks individuals who have recently undergone marked weight changes. As DuBois has put it, "There is no stranger phenomenon than the maintenance of a constant weight under marked variation in bodily activity and food consumption." He has calculated that the maintenance of this constant weight by a man over a period of twenty years involves an adjustment of food intake to total energy expenditure with an accuracy of 0.05 of 1 per cent. "This is an extraordinary exactness which is equalled by few mechanical devices and almost no other biological process."

Increases in weight are not often associated with serious

disease processes and because of the limitation of space the discussion of this class of cases will be omitted.

### NONDESTRUCTIVE WEIGHT LOSS

Weight loss occurs when for any reason expenditure of energy exceeds the supply derived from the food. If an individual is subjected to undernourishment he must secure the extra energy from his body. As long as he has stores of fat (deposit fat in the body) these will be utilized and his body proteins will be protected. This principle is utilized in the dietary treatment of obesity. If sufficient protein is fed to satisfy the appetite and enough carbohydrate to meet the requirements for antiketogenesis and the protection of the liver, the individual may lose weight without symptoms. It may first be called to his attention by the fit of his clothes or the observations of his friends. It is a not uncommon experience to have patients enter the office with such a symptomless weight loss. Our problem then resolves itself into finding the cause for the disparity between energy intake and expenditure. As a rule, we do not find a serious disease but we discover that the appetite has failed him. The weather may have been very hot, or he may have been upset by some unfortunate social or financial incident. With the loss of this regulator his knowledge of food values was not sufficient to enable him to select an adequate quantity of food.

**Case I.**—M. C., Hospital No. 49398. The patient is a white married female, thirty-three years of age, who enters the hospital complaining of:

Loss of 42 pounds in six months.

Attacks of asthma around her menstrual periods.

Fatigability and loss of appetite—four weeks.

The patient has had the attacks of asthma since twelve years of age. No infections or specific sensitizations were found to account for these. Since the attacks were more frequent around her menstrual periods she was given theelin and has been almost completely relieved.

During the last six months she has progressively lost weight and it was her opinion that she was eating well up to one month ago, at which time she became somewhat weak and lost her appetite. The detailed history developed no significant facts bearing on her complaint. The physical examination was negative except for an apprehensive attitude and cold moist hands. The laboratory studies showed no cause for the weight loss.

It seemed probable that the patient was not eating sufficient food and this was tested in the following manner. Her activity was reduced to a known amount by confining her to bed with bathroom privileges. She was next fed a quantitative diet. Experience has shown that a normal individual subjected to this amount of activity will maintain his weight on a diet containing calories 30 per cent above the basal requirements.

Her basal requirements were 1320 calories and the diet which was served to her contained 1718 calories ( $B + 30$  per cent). Her weight at the beginning of a seven-day period was 109 pounds and at the close 111½ pounds. The significance of this experiment was explained to her and she went home convinced that she only had to eat more food in order to stop the weight loss. With the added food the appetite improved and the fatigability disappeared.

#### ACUTE DESTRUCTIVE WEIGHT LOSS

**Case II.**—J. S., Hospital No. 48681. The patient is a tall white unmarried female, twenty-three years of age, who was sent to the hospital by her physician with a diagnosis of myasthenia gravis. Her complaints were:

1. Loss of strength in arms and difficulty in walking due to weakness.
2. Incontinence of urine and feces.
3. Huskiness of voice.
4. Loss of 25 pounds.
5. Insomnia.
6. Numbness in lumbar regions, buttocks, vagina and urethra.

The patient has never been a strong girl. She had rheumatism every winter from the age of twelve to twenty-one, but she has been able to remain employed as a factory worker. Her past history was not remarkable otherwise.

Two months ago she began having severe dysmenorrhea. She was forced to quit work, go home and remain in bed with heat applied to abdomen. During this time nausea was a prominent symptom. A friend of hers recommended two naprapathic doctors (husband and wife) who were successful in treating such conditions. She entered their hospital where she remained three weeks and received the following treatment:

1. Daily irrigations of bladder.
2. Daily colonic flushings.
3. Rubs with alcohol, and massage.
4. Heat to abdomen.
5. Special diet. This deserves careful study, for the first week she received water only, for the second raw fruit juices and for the third carrot salad and other "healthy foods."

During the periods in which she was being massaged and irrigated she received a liberal education in the various parts of her anatomy and special dietary instructions were given which could be followed on her return home. She was impressed with her physical inferiority and the necessity for continuing the treatment rigidly. Five days after her discharge from the naprapathic nursing home she was so weak that she called in a physician who sent her to the Research Hospital with a diagnosis of "myasthenia gravis."

**Physical Examination.**—The examination reveals a slender white female who shows evidence of a marked loss in weight. She has a sad weary expression with a faint icteric tinge to her sclera and a dry skin. She is obviously weak and trembles badly. Her voice is husky and she is so disturbed by the examination that she has difficulty in remaining quiet. Her weakness was so great that she could not walk any distance unsupported and she had difficulty in rising from the lying to the sitting position. The heart was rapid. The reflexes were all physiological and sensation was preserved. There

were no cranial nerve palsies and no difficulty in swallowing. The nurse's notes reported that during the early period of hospitalization she had both *urinary and fecal incontinence*. On vaginal examination hyperesthesia was noted and a *Trichomonas vaginalis* infection was found. The examination otherwise was not significant.

**Laboratory Studies.**—The laboratory studies consisting of blood counts, blood calcium, phosphorus, nonprotein nitrogen, CO<sub>2</sub>, sugar, cholesterol, Wassermann showed no abnormalities. The icteric index had a value of 16 and the urine gave a positive test for urobilinogen for five weeks after her admission to the hospital. The creatine output in the urine (0.6 Gm. per day) on admission was somewhat higher than it was later (0.45 Gm.) when she was taking adequate quantities of food.

**Diagnosis.**—At the time of entrance, the extreme loss of muscle power was striking. However, the cranial nerves were intact. Hence a diagnosis of "myasthenia gravis" was rejected and that of "acute inanition" was adopted. This opinion was confirmed by the neurological consultant.

**Treatment.**—The treatment that was to be followed was obvious but it was difficult because we were unable to secure her cooperation. For several days she ate poorly and offered unsatisfactory explanations of her conduct. It was evident that the naprapaths had instilled into her so many false ideas that a psychiatric consultation was imperative. In the course of two rather extended conferences she unburdened herself of her problems and conflicts. These were easily solved and she at once adjusted herself to the task of eating her way back to health. From now on the problem was a purely medical one.

She presented three outstanding pathological-physiological manifestations.

1. At the outset she had little or no stored fat (reserve calories). When the food was reduced below the maintenance level she secured her energy from the oxidation of proteins (body muscles). To this is to be attributed her emaciation and muscular weakness. The evidence of this destructive action

was found in the increased urinary creatine output. This is the classical picture described in textbooks of physiology and nutrition when lean animals or lean men are subjected to fasting experiments.

This destruction of muscle protein is easily stopped by the addition of sufficient calories to the diet. Up to a certain point, calories arising from carbohydrates are more efficient than those coming from fats.

The patient not only had the problem of stopping the destruction of body muscles but she was confronted with the necessity of rebuilding the muscle fibers requisitioned for fuel. This would come gradually from a surplus food intake. We endeavored to shorten this process by feeding glycine (amino-acetic acid). Glycine has been found to be a valuable agent in restoring muscle function in myasthenia gravis and it was used for this reason. The results seemed to justify its use. The patient's sense of strength and her endurance apparently increased sharply after 15 Gm. were added to her daily diet.

2. The heart muscle evidently had suffered somewhat as the result of the inanition. The rate was rapid (143 per minute) and the electrocardiogram showed evidence of alteration in muscular behavior, slurring of QRS, low voltage, diphasic T 2 and 3. Dyspnea developed rather readily. It was felt that measures used to restore voluntary muscular power would be equally valuable for the cardiac muscle. In addition to this, the patient's activity was reduced by making her an absolute bed patient.

3. This patient's liver was damaged by the starvation process. The evidence of this was found in subicteric tint to the sclerae, the yellow cast to the skin, the increase in icteric index (16) and the presence of urobilinogen in the urine. On admission this was reported as ++++ and one month later as +. It seems that an indispensable amount of stored carbohydrate is necessary for the liver function. When this is absent fatty degenerative changes are induced. When urobilinogen appears in the urine during a period of undernutrition the author believes that this is evidence that the indispensable carbohydrate moiety has been exhausted.

To correct this problem the patient was fed in addition to her hospital tray 100 Gm. of glucose dissolved in orange juice. This was served in four portions and did not interfere with her appetite for other foods. She was able to leave the hospital after fifty-three days in a fair state of nutrition with good muscle power.

#### CHRONIC DESTRUCTIVE WEIGHT LOSS

It is more usual to find destructive weight loss appearing in a chronic form. A group of illustrative cases will be presented.

**Case III.**—E. P., Hospital No. 43977. The patient, a white married female, twenty-one years of age, enters the hospital on a stretcher with a diagnosis made by her physician of Simmonds' disease. Her complaints are:

Irregular menstruation for years.

Pain in the abdomen and back—eighteen months.

Loss of weight—35 pounds in eight months.

Paralysis—two months.

Huskiness of voice to aphonia.

Difficulty in swallowing—two months.

The patient is a girl who has been frail most of her life, her best weight being 115 pounds. She has been the favorite child in the family and has depended on her mother in difficult situations. She dates her first illness of any consequences to November, 1933, one and a half years ago. At this time she developed pain in the abdomen and back which symptoms were attributed to "gravel in kidney." Recovery occurred in two to three weeks and she remained well until her marriage in September, 1934, nine months prior to entrance to hospital.

One month later she had a return of symptoms of 1933. These gradually disappeared but she complained of extreme fatigue and weakness, spending a good portion of her time in bed. At this time the weight loss began and the lower abdominal pains bothered her more and more. Medicine for relief of pain was used. The appetite disappeared and her intake of food diminished.

In April, 1935, two months ago, she rather suddenly developed an almost complete paralysis. She could not feed herself or sit up in bed. She lost rapidly the power to move in bed, and by June 12, 1935, the date of her admission, she was able to swallow only with great difficulty. Her voice was reduced to a whisper. She could manipulate her fingers somewhat, but was unable to shrug her shoulders, or move her arms or legs.

Prior to her loss of muscle power she had numbness and tingling in the hands and feet. The history otherwise was not significant.

*Physical Examination.*—The examination reveals an emaciated female, weighing approximately 60 pounds, who lies helpless in bed and speaks with difficulty in a whispered voice. The general physical examination shows the following significant findings.

Face: dusky pigmentation, no areas of pigmentation in mouth, axilla or inguinal regions.

Heart: embryocardia.

Cranial nerves: bilateral facial weakness. Fundi normal.

Motor: profound weakness of all extremities with wrist drop, foot drop, profound emaciation but no localized atrophy.

Sensory: vague peripheral hypalgesia, vibration sense good.

Reflexes: biceps, triceps, knee jerks and ankle jerks not elicited. Babinski plantar flexion.

Mentality: patient is alert.

*Laboratory Studies.*—Blood: nonprotein nitrogen 31, chlorides 424, glucose 94, CO<sub>2</sub> 54, serum albumin 3.10, serum globulin 1.34, icteric index 12, Wassermann and Kahn negative, white blood corpuscles 6600, red blood corpuscles 5,300,000, hemoglobin 15 Gm. Differential normal.

Spinal fluid: clear. Pandy negative. Pressure not increased, no block, Wassermann and Kahn chloride negative, cell count 8.

Urine: a few pus cells, trace of albumin, positive test for urobilinogen which persisted for two months.

The diagnoses considered in this case were Simmonds' disease, extensive poliomyelitis, Landry's paralysis (infectious myelitis) and peripheral neuritis. A diagnosis of "peripheral neuritis" due to starvation and avitaminosis was accepted largely because of the paresthesias which preceded the onset of the paralyses, the uniformity of the wasting and the paralytic process, and the history of the patient's lack of food intake.

*Treatment.*—The first consideration was the necessity for supplying the patient with adequate food. She had difficulty in swallowing and her physical reserve had reached such a low state that it was imperative to avoid undue exertion. Hence a nasal catheter was passed and she was given small quantities of liquid feedings into her stomach by a syringe at hourly intervals.

Diet				
<i>Foods in grams.</i>		<i>Carbo- hydrates.</i>	<i>Pro- teins.</i>	<i>Fat.</i>
Milk.....	1450	72.5	43.5	50.7
Cream.....	450	18.0	13.5	90.0
Orange juice.....	200	24.0	2.0	
Eggs.....	2	..	12.0	12.0
Sugar.....	40	40.0		
Glycine.....	15	...	15.0	
Yeast.....	4	3.0		
		157.5	86.0	152.7
Calories—2344				
Glucose—222.1				

The patient was in a state of starvation, a factor which had reduced her metabolic rate 20 per cent. She was paralyzed which prevented her from moving in bed, reducing her energy requirements further. For the bed activity of even a comfortable patient caloric requirements may reach a value of 15 per cent. Finally even under basal conditions there is considerable contribution to the basal requirements by the energy expended in maintaining muscle tone. It is safe therefore to state that her energy requirements were 40 to 50 per cent below those for a normal person of her size. The basal

requirements of such a normal person would amount to 2500 calories. On the basis of the above calculation this patient would not be using over 600 calories. One can now appreciate how she has been able to live in the face of what amounted to a three months' starvation period. The diet which was fed her by tube contained 2344 calories and was four times the amount expended on her admission to the hospital.

The tube feeding was continued for ten days. At times she regurgitated and vomited so that it was impossible for her to retain the full quota of food. At the end of this period she was strong enough to take food by mouth at frequent intervals. Progress was satisfactory for eighteen days until the intern who had taken care of her was transferred to another service. She at once began to fret and make all sorts of complaints. She lost her appetite and took her food poorly. At this point the nasal catheter was introduced and feedings continued. With the passage of a week's time and the assistance of the nasal catheter, she was able to forget her attachment to the intern sufficiently to return to oral feedings.

About five weeks after her admission she again was badly upset when her husband failed to pay her an expected visit. Loss of appetite and vomiting followed. The nasal catheter cured this in three days.

After a three months' stay in the hospital she was discharged with recovery advanced sufficiently so that she could move freely in bed, and feed herself with some assistance. There were a number of conferences between her and the psychiatrist. At the conclusion of these conferences it seemed quite evident that the patient was physically and mentally inadequate to meet her problems.

The sequence of events which led to the condition presented on entrance to the hospital may now be reconstructed. An attack of cystitis which would not have disturbed an ordinary person put her to bed for two weeks. She then became tired out and found it easier to remain in bed than to be up. It was easier to eat little or nothing, an inadequate diet, than to get up and prepare adequate food. Various neuritic pains

appeared for which she took medicine and continued to eat inadequately. Finally the full picture of emaciation and paralysis appeared. It was so extreme that her physicians made various incorrect diagnoses and she was passed from one to another as a hopeless case of Simmonds' disease. It is interesting to note that the correct diagnosis of peripheral neuritis on the basis of avitaminosis was made by the intern at the close of his careful history and physical examination. Again I wish to emphasize the fact that there is no substitute for a careful history and examination of the patient if correct diagnoses are to be made.

**Case IV.**—H. R., Hospital No. 36346. The patient presents an extreme degree of weight loss induced by ill-advised methods of weight reduction and the lighting up of a fatal disease.

The patient, a thirty-four-year-old female, was well but obese until May, 1933, at which time she undertook a reducing régime. She took daily a dose of saline cathartics which she saw advertised and which was purchased at a drug store. The salts spoiled her appetite so that she could not eat. The food was gradually restricted to one meal per day consisting of cheese, coca-cola and soda pop. The use of the salts was continued until Thanksgiving at which time she could retain no food. About January 1st (six weeks prior to admission), she vomited even water. Since January she has had a productive cough and she has suffered from numbness of the fingers and toes. Her total weight loss has amounted to 150 pounds in eight months. The patient continued to vomit after admission to hospital; the food was returned immediately after it was eaten. x-Ray of esophagus showed the typical cigar-shaped shadow seen in cases of cardiospasm. The sputum was large in quantity, offensive in odor, contained fusiform bacilli and spirochetes. Just prior to death tubercle bacilli were found. x-Ray showed multiple cavitation in the upper and lower lobes of the right lung. The course was steadily downward in spite of all therapeutic measures (nasal oxygen, nasal catheter feeding, therapeutic pneumothorax).

On autopsy the large cavities in the right upper and right lower lobes were found associated with numerous other small areas of abscess formation. The peribronchial glands were enlarged, soft and apparently seminecrotic. It is interesting in this connection to note that the Mantoux test gave a strongly positive test with an area of actual necrosis in the center.

This is a most instructive case because it shows the very great importance of the food elements in the body's resistance to disease. There was a maximum of exudation and transudation. The migration of organisms through the blood vessels and tissues was unimpeded. The picture in the lung was that of spontaneously developing areas of liquefactive necrosis. The entire lungs and lymphatic system were undergoing solution comparable to the melting of ice. It would be a highly speculative procedure to assign to any particular food element responsibility for resistance to infection, but the dissolution of this patient's body was accomplished by the simple process of withdrawing adequate quantities and kinds of foods.

#### VITAMIN B<sub>1</sub> AND B<sub>2</sub> DEFICIENCY

Case V.—E. M., Hospital No. 42573. In this patient the weight loss was not so marked but the destructive effect on the body was none the less significant.

This sixty-two-year-old woman entered the hospital on March 12, 1935, and told this story. She became sick in June, 1934, but a physician was not consulted until October, 1934, and no medicine was taken prior to that time. At the onset there was numbness, pain and swelling in the hands and feet. Her physician made a diagnosis of arthritis and prescribed cinchophen. The patient's condition grew steadily worse, her activities were reduced by the pain. On entrance she had not only swelling of the hands and feet but she was also dyspneic and orthopneic and in a low-grade state of confusion and delirium. A diagnosis was at once made of "multiple peripheral neuritis" but we were uncertain as to the etiological agent. Since the process was so painful, arsenic

was suspected. Her medicines were checked but none of them contained arsenic. The hair contained only a small amount. However, she was given sodium thiocyanate intravenously without improvement. So this diagnosis was abandoned. One next considered an alcoholic neuritis or alcoholic pellagra. She not only had extreme pain as noted above but she developed a severe diarrhea as soon as food and oral medications were begun. The patient and her husband both denied the use of alcohol in any form, but they admitted that for six months prior to the onset of her symptoms, they had lived on reduced rations of food. They were too proud to go on relief and were trying to weather the storm alone. Now that it has been established that the cases of alcoholic pellagra are due to dietary deficiency, the patient preferring to drink alcohol rather than to eat, it is easy to ascribe a painful multiple neuritis to avitaminosis directly without the necessity of invoking alcohol as an etiological agent. This patient may therefore be classified as deficient in both  $B_1$  and  $B_2$ .

Because of the irritable gastro-intestinal tract, it was necessary during the early stages of her hospitalization to resort to intravenous injections of fluid to protect her water balance. When the diagnosis became clear, she was at once placed on intramuscular injections of liver extract, a form of therapy which has been found valuable in alcoholic pellagra. Improvement was progressive and rapid. Later physiotherapeutic treatments gave her great comfort.

#### VITAMIN $B_1$ DEFICIENCY

**Case VI.**—M. S., Hospital No. 48221. The patient is a sixteen-year-old girl who has spent her life on a farm. She entered the hospital March 3, 1936 with the following complaints.

Swelling, discoloration and gangrene of both feet—one month.

Expectoration of clotted blood at irregular intervals for two years.

Swelling of fingers—four months

Her health was fair until December, 1934. At this time swelling of the feet and ankles appeared in the morning and became progressively worse so it was difficult to get her shoes on by evening. There was a purplish discoloration of the feet and ankles and a loss of feeling. She went to bed and remained there until May, 1935. Contrast baths were tried but discontinued because of the pain. Various types of ointments and salves were ineffectual.

In spite of an alleged good appetite during her five months in bed she lost 25 pounds. In May, 1935, she became more active, the color of her feet improved and swelling decreased. Throughout the summer she felt tired and lacked energy. In November, 1935, the feet again became swollen and purple, especially the toes. The skin over the feet became hard and felt "petrified." Intermittent pains appeared in the toes. The small toe of left foot turned black and was removed one week ago. In January large blisters developed on both feet which discharged a bloody fluid at times, at other times a straw-colored fluid. More recently (five weeks) the fingers became purplish with white round hard tips. She denied having had frostbite at any time.

Two years ago she began spitting up thick bloody clots in the morning at four- to six-week intervals. At this time she bled from the nose also. On further questioning she states that she has had a good appetite and has eaten well. There is no history of the development of bilateral blanching of hands or feet on exposure to cold.

The examination reveals a girl who is fairly well-nourished but much underdeveloped for her age (sixteen). She had the appearance of a child eleven years of age. She is not in any acute pain. The hands and feet have been described. There is a lack of hair and development of secondary sexual characters.

The neurological examination showed the cranial nerves normal except for an internal strabismus on the right side. The upper extremities were normal as regards sensation, power, tone and reflexes. There is weakness of the dorsiflexion of

ankle, plantar flexors of ankles, and corresponding weakness in the toes. Knee jerks increased, ankle jerks normal. Flexion to Babinski, calves tender, Achilles tendon quite tender. Patient cannot walk on heels with toes off the floor. Plantar surfaces hyperesthetic, trophic ulcers on feet.

The laboratory studies were complete.

Blood, hemoglobin 12.3 Gm., red blood corpuscles 4,820,000, white blood corpuscles 7.6, differential normal, coagulation time ten minutes, bleeding time six minutes, clot retracts normally, platelet count 340,000.

*Blood Chemistry.*—Glucose 90, nonprotein nitrogen 40, CO<sub>2</sub> 52, cholesterol 222, calcium 9.2, phosphorus 6, Wassermann and Kahn, negative.

Oscillographic studies showed normal findings for both legs.

*x-Ray Studies.*—Right foot showed decalcification which is probably in the nature of secondary atrophy due to disuse or trophic disturbances.

Lower spine no pathology such as a spina bifida.

Chest negative.

Biopsy of leg muscle showed normal vessels.

*Diagnosis.*—Raynaud's disease was eliminated because there was no history of intermittent blanching of feet and hands on exposure to cold.

A very early onset of hypertensive disease was ruled out by the normal oscillographic response and the normal microscopic appearance of blood vessels in the biopsy.

Trophic changes in feet secondary to a vertebral anomaly was eliminated by x-ray plates of spine.

Since the patient had evidences of bilateral muscle weakness, trophic changes (gangrene and blebs), tendon tenderness, hyperesthesia of plantar surfaces, a diagnosis was made of "peripheral neuritis" probably due to lack of antineuritic vitamin.

*Treatment.*—She was continued on ward diet and given brewers' yeast, 6 Gm. per day. Her recovery began at once and was completed at the end of three months when she was discharged.

This case is extremely interesting since it records a case of vitamin B<sub>1</sub> deficiency in a young child who has been reared on a farm where presumably there was an abundance of foods containing the antineuritic vitamin.

#### VITAMIN C DEFICIENCY

**Case VII.**—L. M., Hospital No. 47499. Present complaints: vomiting—three years.

Lower abdominal cramps—three years.

Localized pain in left upper quadrant.

Hematemesis—four months.

Epigastric pain—four months.

She had stomach trouble off and on all her life. At age of fourteen years she almost drowned and since then her troubles have increased. Chronologically the events may be summarized.

Age sixteen, 1931 appendectomy, recovery poor; remained in bed for six months.

Interval of activity three months' duration, terminated by vomiting, returned to bed for six months, at end of which time a diagnosis of pulmonary tuberculosis was made. Entered sanatorium in fall of 1932 and remained a patient until January, 1936, except for a short period when she was in hospital for surgical treatment. During the period of sanatorium care she has had a continuous abdominal problem. At times this was characterized by cramps and vomiting, at other times diarrhea and bloody stools. In 1933, an abdominal exploration was made and a portion of bowel removed because of tuberculous enteritis. In 1934 tonsils were removed. In September, 1935, the vomiting increased to the point at which she lost 2 meals per day. In November, hematemesis of small amounts began and has continued to the present. There is also associated with this bloody bowel movements. She enters the hospital on diet management consisting of milk and cream and alkaline powders.

The physical examination reveals a young white female whose previous weight has been 115 pounds, whose expected

weight is 130, but whose actual weight is 87 pounds. She hiccoughs persistently during the examination and has vomited one time. She looks worried and complains chiefly of abdominal pain and soreness. The examination except for the abdomen and general appearance was not remarkable and will be omitted. The gums were in fair condition and were not bleeding and did not contribute the blood to the sputum.

*Laboratory Studies.*—Urine, acetone ++, albumin trace, urobilin 0.

Stools, blood ++.

Blood, hemoglobin 11.2 Gm., red blood corpuscles 4,000,000, white blood corpuscles 4400, platelets 250,000 differential normal, leukocyte count later dropped to 9850, hemoglobin remained unchanged. Wassermann negative.

Chemistry, normal limits.

Sputum, negative for tuberculosis and Vincent organisms.

*x-Ray.*—Chest, increase in shadows of hilum no parenchymal changes.

Genito-urinary tract, esophagus negative. No organic lesion, irregular distribution of barium in intestine with formation of isolated masses suggestive of intestinal adhesions and spasticity.

Barium enema, no obstruction or filling defects. Kidneys, intravenous pyelograms, no apparent pathology. Proctoscopic examination—no ulcerations or pathology up to 25 cm.

Esophagoscopy—no pathology and no indication as to source of bleeding.

*Diagnosis.*—The diagnosis in this case offered many possibilities. She was sent to the Research Hospital by her physician on the assumption that she had an intractable tuberculous enteritis and that an intestinal obstruction was imminent. It was felt that the case was one that would require surgery. One had only to read this patient's history to realize that we were dealing with a food deficiency. She might have tuberculosis but there could be no doubt that her diet was inadequate in calories and in other essentials. Hence it seemed wise for the time being to fix our attention on the nutritional problem. This

view was further justified when no ulcerations were seen in the esophagus and rectum and no organic diseases of stomach was revealed by x-ray. The bleeding was attributed to a capillary disease since the platelet counts and bleeding time were normal. Since vitamin C (ascorbic acid) regulates the colloidal conditions of intercellular substances, it was clear that among other things, we were dealing with a deficiency in this vitamin.

*Treatment.*—The management of this patient taxed our ingenuity and patience to the limit. The plan followed will be briefly summarized:

1. By repeated interviews on the part of the house officers, she was persuaded that she had a chance to get well providing she would cooperate. This was not an easy task since we were dealing with a young girl who had been bedridden from sixteen to twenty-one years of age, had spent four years of this time in a sanatorium for tuberculosis and had been subjected to 3 surgical procedures of questionable value (appendectomy, resection of bowel and tonsillectomy).

2. The fluid balance at first was maintained by almost daily injections of 5 per cent glucose in buffer solution.

3. Blood transfusion.

4. Utilization of all the known tricks to keep her from vomiting.

5. The daily or every other day intravenous injection of ascorbic acid (vitamin C) in 100- to 200-mg. doses.

The bleeding stopped within a short time of the use of the ascorbic acid. Her pain subsided and she left the hospital at the end of four months, eating the ward diet and with a gain of 8 pounds.

#### GENERAL CONSIDERATIONS

If, in treating the sick, one can keep before him the conception that there are certain indispensable requirements for the proper functioning of the body and that these must be met in sickness more rigidly than in health, he will have a most valuable aid in therapy. He will find that many symptoms

presented are not necessarily a part of the disease but they may be due to the neglect of some of the common laws of nutrition. If these are corrected the disease loses its terrors. The great outstanding contribution of this nature was made by Coleman in 1912 when he described the treatment of typhoid fever patients with high calorie diets.

Suppose we consider for the moment the symptom of incontinence of urine, urinary retention and incontinence of feces. When such symptoms are mentioned to a physician he at once begins to think of a serious disease process, and yet I have been struck by the frequency with which these occur in such cases as I have been describing. All of the patients who have entered the hospital with profound undernutrition and wasting have had incontinence of urine and feces, and have recovered from these by being fed. Time does not permit me to cite the details of the records of 2 other cases suffering from malnutrition who had urinary retention. Both of these patients were submitted to cystoscopic studies and there were no evidences of obstruction found and there was no cord bladder present. When they were in nutritional balance the bladder functioned perfectly. After all the disease or infection may be producing its symptoms by destroying vitamins or interfering with their function. It is logical to believe that the vitamin in question might be furnished in such large doses that the infection could not completely rob the body of its action. Then the patient would be relieved of his annoying symptom in spite of the fact that he may not be cured of the disease. From this viewpoint the physician would be constantly bending his energies toward the objective of keeping the bodily processes functioning physiologically rather than allowing them to become pathological.

It would seem unwise to close this discussion without calling attention to the large psychic element in nutrition. The vegetative mechanism is constantly subjected to reflexes originating in the mental field. If these are pleasurable, there is a facilitation of digestion, if they are not there is inhibition. A disturbing bit of news is received and the individual loses

his appetite, if the adjustment is difficult he may become nauseated and vomit. One has only to look at the nervous worried patients who are suffering from anxiety neuroses to realize the great blockade that the mind offers in these patients to maintenance of a normal nutritional state. We may force food on them, but we could accomplish our ends much better if the anxiety status could be removed.

The great majority of nutritional problems arising in the young spring from some abnormal psychic reaction. These may be the results of improper education or unfortunate circumstances, but rarely is the nutritional problem met until the psychic adjustment is made. Reference to the cases cited will show the large part played by the psychiatrist in their treatment.

## CLINIC OF DR. C. A. ALDRICH

### CHILDREN'S MEMORIAL HOSPITAL

---

#### THE USE OF VITAMINS IN CHILDREN'S DIETS

It is quite natural that physicians interested in the care of children should have responded early to the implications resulting from the discovery of the various vitamins. because the most marked vitamin effects are upon the growing animals. Antagonism tinged with incredulity was the first reaction. later came gingerly acceptance, and the present attitudes range from extreme skepticism to extreme enthusiasm. The extent to which various clinicians use these accessory food factors in their actual work, therefore, varies considerably. It is the purpose of this paper to outline the known facts about their functions so that the reader may use his own judgment in making use of these therapeutic and preventive agents.

#### GENERAL GROWTH EFFECTS

It may be stated at the outset that practically all of the known vitamins seem to be necessary in order that general growth of the body may proceed. In view of the extremely small amounts necessary to permit of general growth, it is unlikely that they supply necessary building stones in the process. It seems more probable that they act as catalysts in the chemical processes characteristic of growth. It seems quite well established that the amount of growth is not quantitatively dependent upon the dosage of administered vitamins. In other words, the statural possibilities of an individual are not dependent upon quantities of vitamins in excess of those necessary to catalyze the growth reaction. This fact should make the physician skeptical about enthusiastic statements

made by experimenters as to increases in growth due to vitamins. In one extreme case I recall that an increased growth of 100 per cent was claimed to be due to treatment with vitamin B. This is manifestly impossible in normal animals, and if it were possible would be highly undesirable since there is considerable evidence to show that abnormally rapid growth tends to shorten the life span.

One would expect to find increased rate of growth as a result of vitamin feeding only when the test group of individuals was compared with a control group kept under conditions of vitamin deficiency.

#### EFFECTS UPON THE GROWTH AND FUNCTION OF SPECIFIC TISSUES

Even more startling than knowledge of this general growth-promoting function is the fact that each vitamin seems to have a specific influence on the histologic development and function of definite tissues. Therefore, in the case of each vitamin, it is possible to demonstrate pathologic lesions resulting from deficiency diets. In this field, the effect of vitamins is to a certain extent quantitative. The severity of the pathologic changes vary with the degree of the deficiency and its duration.

It is probably true that the function of many of the endocrine glands is related to specific vitamin changes, but this field of investigation has not yet been explored adequately. The parathyroids are known to be associated in function with vitamin D and the suprarenals probably complicate the problem of vitamin C. Many vitamin problems may be cleared up when their relation to hormones is understood.

#### VITAMIN A

Because it was for a long time unsuspected that there was more than one fat-soluble vitamin and because we did not realize that vitamin A could be synthesized in the body from its precursor carotene, accurate observations about this substance were delayed for many years. It has been definitely shown that it is essential for general growth and for life itself in

experimental animals. The following table summarizes the specific local changes found in vitamin A deficiency states.

- (a) Xerophthalmia and hemeralopia (night blindness).
- (b) Secondary infectious processes due to abnormal epithelium in the upper respiratory tract, lungs, glands and genito-urinary tract.
- (c) Renal lithiasis.
- (d) Sterility.

All of these changes are due primarily to keratinization of mucous membranes, which is the typical histologic lesion demonstrable.

Since it is true that vitamin A and its precursor carotene are liberally supplied by nature in ordinary foods, it is evident that absolute deficiency of this food factor probably does not occur in human beings. Under extreme conditions of fat deprivation such as may happen among poverty-stricken people and during wars, partial deficiencies may be fairly common. The eye conditions have been reported frequently from Scandinavian countries.

The most controversial point about vitamin A has been concerned with its relation to infectious processes. It was called the "anti-infectious vitamin" by many men and many observations substantiated this description. It was not until the demonstration of its mucous membrane effects, in preventing the development of keratinization, that the true function of this vitamin in preventing infections became clear. It now seems beyond reasonable doubt that protection from infection is not dependent upon any immunologic reaction in the blood or tissues but does result from the maintenance of normal mucous membranes.

It is easy to understand how the substitution of squamous cells could lead to local infections of considerable severity. Tyson and Smith list the following changes due to vitamin A deficiency: "metaplasia of cuboid or columnar epithelium in certain parts of the body, epithelial hyperplasia in various structures in this order; sublingual glands, submaxillary glands, epithelium of the renal pelvis and of the trachea and bronchi."

From a practical standpoint, the most important consideration today is whether or not prevalent "colds" are due in part to avitaminosis A. The question has not yet been satisfactorily answered in spite of considerable research, as many experiments have resulted in contradictory or equivocal findings. In my opinion the problem resolves itself into one of socio-economics, because the only type of people at all likely to be undernourished with this substance are those who are poverty-stricken. It may be of clinical importance that the babies of such people have a much higher morbidity and death rate from mucous membrane infections and their sequelae than is suffered by the young infants of the more privileged social groups. Since these poor mothers and babies often exist on diets containing very little vitamin A, it is conceivable that avitaminosis exerts a controlling influence here. At any rate it would seem but just to attempt an en masse improvement in the dietary supply of this factor in the poverty groups. Whether or not concentrates will be necessary or advisable awaits further knowledge as to dosage. From the standpoint of the baby's diet, much has already been accomplished in the routine administration of cod liver oil, an excellent source. The weak spot in our plan is found in the extremely poor prenatal diets eaten by most of the mothers.

The sterility which results from vitamin A deficiency is also produced by epithelial changes, keratinization of the membranes of the reproductive system. There is decreased or absent spermatogenesis in the male, whereas in the female the changes in the epithelium seem to make implantation of the fertilized ovum impossible. These abnormal conditions in both male and female are reversible so that adequate administration of vitamin A will restore the lost sexual function.

It is often forgotten that during lactation there is an increase in the need for this substance in the mother's diet.

It should be noted that mineral oils should not be taken at the same time that vitamin A is administered, because the fat-soluble vitamin is absorbed by the larger quantity of mineral oil and is thereby prevented from assimilation into the

body. More rarely, it has also been observed that certain abnormal intestinal and hepatic conditions have interfered with its utilization after it was thought that adequate dosage had been prescribed.

Summarizing the practical importance of this vitamin, then, it might be said that absolute deprivation is rarely possible in human beings because of its widespread distribution, but that partial deficiency is known to occur often enough to have made it a matter of considerable importance in certain countries under normal conditions and in many during wars and famines. Whether or not a relative deficiency of vitamin A is an important factor in the prevalence of mucous membrane infections and their more serious sequelae is yet to be determined. Adequate knowledge as to dosage is not yet available, but it is customary to assume that the amount found in three teaspoons of standard cod liver oil is a sufficient daily dose. The inclusion of cream, milk, butter and green vegetables in the diet should make concentrates unnecessary, in normal children.

#### THE VITAMIN B COMPLEX

In spite of the fact that one of the members of this water-soluble group of vitamins was the first to be isolated, the exact functions of these accessory food factors are less well known than are those of more recently discovered substances. There are probably several as yet undifferentiated members in this group, but at the present time it is possible to discuss intelligently only two, vitamin B<sub>1</sub> and G (P or B<sub>2</sub>). Vitamin B<sub>1</sub> is heat labile and G is heat stable.

#### VITAMIN B<sub>1</sub>

This has been called the antineuritic vitamin because polyneuritis is the best known pathologic state caused by its lack. Beriberi is the best known human disease resulting from avitaminosis B<sub>1</sub>, and is prevalent in oriental countries.

It has been amply demonstrated that animals on diets deficient in this vitamin do not grow normally, but whether or not this is due to pure avitaminosis is a controversial point. Many observers feel that the lack of growth observed is due

to inanition resulting from the anorexia which commonly follows diets deficient in vitamin B. In fact, it has been claimed that all of the pathologic lesions seen in B<sub>1</sub> avitaminosis can be duplicated in starvation.

The work of several observers indicates that the mental growth of young animals is retarded if their mothers were kept on deficiency diets during pregnancy. Unfortunately this condition seems to be irreversible, since the postnatal administration of the vitamin does not restore their mental function to normal.

Changes in the hematopoietic system are likewise found, but here again it is possible that inanition plays a rôle. It may be of significance in this regard that many of the newer liver extract preparations are found to be excellent sources of this vitamin.

The developmental changes include myelin degeneration of nerve fibers extending to voluntary muscles, degeneration of the fibers of Auerbach's plexus, focal lesions in the brain and pons, hypertrophy of the heart and suprarenals, and atrophy of the mucous and muscular layers of the stomach and intestines. Hemorrhages into the osteogenetic system seem to be a part of the picture. Consideration of these lesions will explain why some men have emphasized that this vitamin is of functional rather than of structural importance, and will explain the asthenia seen in some of these patients.

It has been demonstrated repeatedly that during lactation there is marked increase in the demand for vitamin B<sub>1</sub>. This is because the vitamin is not excreted quantitatively in the mother's milk.

#### VITAMIN G (P, B<sub>2</sub>)

While it is probable that in their relation to general growth and appetite this vitamin and B<sub>1</sub> are similar, other specific functions are quite different. In vitamin G deficiency, skin and mucous membrane lesions are found in addition to the nerve degenerations. In experimental animals, dermatitis, alopecia, stomatitis, glossitis, and cataract have been found due to deficiency of this vitamin alone.

There is still considerable controversy over the question as to whether or not pellagra is a pure avitaminosis G. or P. as those on the affirmative side choose to call it. Certainly the two conditions have been closely linked together. Pellagra can be prevented by administering vitamin G, and the disease frequently occurs in those living on diets poor in this factor. Treatment with the vitamin has been successful in those patients whose disease was of relatively short duration, but has been disappointing in those who have been ill for long periods of time. It is contended by those who defend the deficiency nature of the disease, that the nerve and cord degenerations resulting are irreversible changes so that cure after sufficient time has elapsed for them to take place is impossible under any conceivable management.

Summarizing the points of practical importance about the vitamin B complex it should be noted that the vitamins in this group are of primary importance in general growth and for the maintenance of a good appetite, at least in experimental animals. Without an adequate supply, degenerative nerve lesions develop centrally and peripherally. In addition beriberi and probably pellagra are caused by avitaminosis B.

While the dosage has not been adequately worked out on human beings, it is comparatively easy to administer these factors either in the normal diet by attention to the articles of food offered, or by the use of concentrates such as brewer's yeast tablets, carbohydrates with added vitamin B such as are advised in infant feeding, or in liver extract prescriptions. It is my personal feeling that, since no evidence has been offered that there is any likelihood of overdosage, its routine administration to young infants is indicated.

#### VITAMIN C

Although scurvy, the best known condition associated with vitamin C, has been recognized for many generations as a deficiency disease, this factor was among the last to be discovered. Nevertheless, recent chemical discoveries have compensated for the delay. Recognition of its exact composition

has resulted in making cevitamic acid available in pure form.

General growth and life itself are dependent upon a sufficient amount of this factor in the diet. After its elimination, experimental animals begin to lose weight in about ten days and usually die in from three to four weeks. Because it is an extremely difficult thing to find a human diet which is absolutely deficient in this vitamin, patients with scurvy have usually run a longer course than this before death.

All of the pathological changes found in vitamin C deficiency are probably dependent upon one fundamental lesion, capillary damage, a failure in the laying down of cement substance between the endothelial cells. In listing the various lesions seen one should include edema, serous effusions, hemorrhages into the skin, parenchymatous organs, bones and periosteum, cardiac hypertrophy, enlargements of the shafts of bones particularly at the metaphyses, fractures, epiphyseal separation, beading of the ribs, and degeneration of nerves.

Because of the similarity of the nerve lesions in avitaminosis B and C, many men believe that these two water-soluble vitamins are intimately related.

Since the isolation of cevitamic acid as pure vitamin C it has been possible to estimate its concentration quantitatively in the blood stream. This advance makes unnecessary the cruder attempts to demonstrate its deficiency such as the various capillary resistance tests.

Much work has been expended in trying to estimate the degree of importance which should be attached to this vitamin in regard to dental caries. Enough has been accomplished so that we know it to be a factor, but it is undoubtedly only one of the many concerned in this complicated problem.

Critical consideration makes it evident that because of its fundamental importance vitamin C should be considered in the arrangement of any diet. It is easily administered in fruit juices or raw vegetables. As a practical point which should be kept in mind in these days of evaporated milk's popularity, it should be repeated that a potent source of vitamin C should

be given all children on an exclusive cooked milk diet. It is not uncommon to see patients with scurvy in our children's hospitals nowadays because this fact is overlooked. While amounts as small as 1 or 2 teaspoons of orange juice have been known to cure scurvy, the optimal dose is probably several times as great. Most children tolerate from 3 to 4 ounces or more daily.

#### VITAMIN D

This factor did not emerge from obscurity until comparatively recently because it is associated in nature quite closely with vitamin A, and for many years their relative functions were confused. Thanks to the accurate observations of Melanby, McCollum, Huldshinsky, Hess, Steenbock and others, the importance of ultraviolet light in the genesis of this factor was discovered. As a result, activated ergosterol, known in this country as viosterol, can be produced in large quantities. This is a close approximation to, but is not a pure vitamin.

Because it is fairly well stored in the body, vitamin D may be eliminated from the diet for a considerable time before general growth is disturbed, but ultimately it has been found necessary for this process.

The local or specific lesions resulting from relative or complete deficiency are all due to insufficient delivery of calcium and phosphorus to the bones. The bones are soft and fragile and present various deformities most marked in the epiphyses where the most rapid growth normally takes place.

The exact pathogenesis of rickets, avitaminosis D, is still unknown, although it is recognized that in some way this vitamin assists the body in assimilating and retaining calcium and phosphorus so that their level in the blood stream is sufficient for normal osteogenesis.

When massive overdoses are given, thousands of times the average generally used, the amount of these minerals found in the blood stream may reach pathologic proportions and lead to untoward effects. This result can hardly occur, however, when doses approximating those usually prescribed are administered.

Tetany, since it is associated with a low level of calcium in the blood, is directly related to vitamin D.

It is also quite evident that an adequate amount of this factor is needed for the formation of normal teeth and jaws.

From a practical standpoint it is interesting that vitamin D in the form of cod liver oil had proved itself so valuable from a strictly clinical standpoint that its routine use was advocated long before it was known to exist as an accessory food factor. It is undoubtedly true that in all temperate climates vitamin D should be administered routinely to children, as exposure of the skin to ultraviolet light is usually insufficient to permit of normal absorption of the vitamin.

It is generally felt that from 1 to 3 teaspoons daily is the optimal dose. Various concentrates such as viosterol, cod and other fish liver oil concentrates, and various fish oils fortified with viosterol, flood the market so as to confuse even the best informed physicians. I can only advise that in considering the dose to be prescribed, these figures be translated into plain cod liver oil equivalents. In general, since cod liver oil has proved itself so valuable empirically, the more natural products should be preferred to those artificially prepared. During the summer months this factor may be discontinued if the body is exposed frequently to sunlight.

#### VITAMIN E

This substance was the last of the fat-soluble vitamins to be isolated. As yet it has not been shown an absolute necessity for general growth except in the fetus. It is unusually well stored in the body so that the experiments on this problem are hard to evaluate.

The importance of this food factor became evident when sterility was produced in experimental animals on diets which contained adequate amounts of the other known vitamins. It is an extremely interesting fact that the sterility which results is an entirely different process in male and female animals. It is due, in the male, to degeneration of the germinal epithelium. In females it is apparently a result of fetal death, as the

embryos are all absorbed. If a single large dose of the vitamin is administered early to pregnant animals, enough of the factor is stored to permit of normal gestation.

The degenerative changes found in the germinal epithelium of males are irreversible so that in most animals readministration of the vitamin does not restore their ability to impregnate. The secondary sex characteristics are not affected by this deficiency.

Sterility due to deficiency of vitamin E has not been shown definitely in human beings, but suggestive cases have been reported and it remains a possible cause.

### GENERAL CONSIDERATIONS

After reading such a résumé as this of the effects of the various vitamins, one's first response is confusion. One wonders how the race grew up when it was ignorant of all this startling knowledge. Such questions as to what degree avitaminosis was prevalent in past times, what vitamins are yet to be discovered, how many pathologic processes as yet of undetermined origin will be found due to deficiencies, and just what is a sensible attitude to take now, crowd into our thoughts.

The facts cannot be denied. Many important disease entities have been adequately explained and their treatment established. We must admit the importance of these substances for normal growth and life itself. Shall we then rush in and see to it that these substances in the form of known concentrates are routinely administered to children?

It seems to me that the lesson to be learned from all this is more fundamental. All of these substances are and have been freely available to human beings in the varied diets they naturally consume. It is inconceivable that the race could have evolved to its present point if the necessary factors for growth were not so easily available. The difficulty has arisen from our handling of the food stuffs. In our recent use of highly processed and cooked viands we can now see that many of the most important accessory factors are destroyed. It seems to the author that the thoughtful physician of today

must see to it that the children he cares for are taught to eat a wide variety of foods as little changed from their natural state as possible. In this way one would expect to supply adequate amounts of the known vitamins and also the ones which future investigators may discover tomorrow. Such a program will entail not only offering these foods to children but also considerable modification of adult diets because children will like to eat what they see others consuming. It will involve considerable attention to the growing appetites of youngsters. Fortunately most children like foods in a relatively unrefined state better than they do more sophisticated foods. Highly seasoned and sweet articles of diet should be withheld as long as possible from their attention.

The use of vitamin concentrates will be advisable for treatment of avitaminosis, but with the possible exception of vitamin D will probably not be necessary routinely if the general public will insist on a natural diet which is adequate. If the present tendency toward refinement of foods persists and carbohydrates remain as popular as they have been for the last fifty years, it is conceivable that routine administration of concentrates may become necessary.

CLINIC OF DRS. CHARLES A. ELLIOTT AND  
WALTER H. NADLER

PASSAVANT MEMORIAL HOSPITAL

INANITION

INANITION or emaciation is a symptom due to starvation or to disease, or may be the result of both disease and starvation. The basic cause is an inadequate diet or the faulty utilization of an apparently satisfactory diet. The metabolism of absolute starvation has been studied in professional fasters and in experimental animals. These studies emphasize the fact that food is necessary for the preservation of life and that if it is not obtained the body tissues will be utilized. To protect these tissues the basal metabolism assumes a definitely lower level. The carbohydrate stored as glycogen and the "deposit protein" are oxidized first; then the body fat is drawn upon and finally, the body protein. The tissues of greatest physiological importance are spared as long as possible. When the most vital organs are sapped, death occurs.

Clinically we are concerned with semistarvation (incomplete inanition). This may be due to a diet inadequate in quantity or in quality, or deficient in both respects. Many functional disorders and pathologic conditions lead to impairment of appetite and an inadequate intake of food, or to faulty utilization of the diet. Diseases of certain endocrine glands which are fundamentally concerned with nutrition quickly lead to emaciation.

The following patients and case reports are presented to illustrate various types of inanition:

**Case I.**—This patient is forty-five years of age. Her height is 66½ inches and her weight 106 pounds. She has been an example of constitutional leanness, always underweight but able to carry on her duties as a nurse without undue fatigue. She married at forty years of age and since that time has kept house. The past year brought considerable nervous tension due to several deaths in her family and especially, to the unaccustomed care of an adopted child. She lost much sleep, developed anorexia and exhaustion, and lost weight. In the past six months the menses have been delayed and prolonged, but scant. Prior to admission to the hospital for a diagnostic curettage she flowed for five weeks. There have been no hot flashes.

Examination shows an emaciated woman with scaphoid abdomen. Her nervous facies suggests hyperthyroidism although there is no goiter clinically; her pulse is slow and tremor of the fingers is absent. Physical examination is otherwise negative. Blood pressure 130-80. Blood examination showed slight secondary anemia. Wassermann negative. Urine normal. Blood calcium 9.95 and cholesterin 294 mg. Of interest is the fact that on June 9th her basal metabolic rate was -41 per cent (weight 101½ pounds); on June 11th the basal metabolic rate was -27.9 per cent (weight 104 pounds); and on June 15th the metabolic rate was -16.3 per cent (weight 106 pounds). The change in the basal rate was due solely to bed rest, a high caloric diet and sedatives; no thyroid medication was used. In two weeks at home on rest periods, diet and iron, she has gained 7 pounds in weight and feels less fatigued.

**Diagnosis.**—Constitutional leanness; functional bleeding of the menopause; semistarvation due to anorexia from nervous causes, producing extreme exhaustion and a low metabolic rate.

**Case II.**—This patient, a lumberman, forty-five years of age, was admitted to the hospital because of weakness, loss of 40 pounds in weight, vomiting, a pressure distress in the epigastrium, and constipation. Weight 126 pounds, height 69 inches

Gastro-intestinal symptoms had been present for five years, but he had had remissions of as long as four months' duration. Symptoms appeared in the following sequence: constipation, belching relieved by induced vomiting; regurgitation of sour material which caused vomiting; a sensation of pressure in the epigastrium, relieved by vomiting. The belching and pressure occurred chiefly about two hours after supper and were apt to disturb him during the night. The symptoms gradually became worse. Six months before admission all of his remaining teeth were extracted; thereafter he subsisted on a liquid diet and during this period he lost 25 pounds in weight.

Examination revealed a muscular but emaciated, edentulous man. Blood pressure 90-60. The abdomen was distended: peristaltic waves, apparently of gastric origin, were observed. No masses were palpable and the liver and spleen were not enlarged. Thyroid normal. Heart and lungs negative. Moderate secondary anemia present. Wassermann negative. Aspiration of the stomach at 8:30 p. m. yielded 1000 cc. of food material; sarcinae were found. Stools contained no blood.

The attempt was made to improve his condition before operation by frequent small feedings, but frequent aspirations of the stomach and loss in weight indicated that the stenosis of the pylorus was almost complete. A blood transfusion was given and a laparotomy performed. An old ulcer was found in the pyloric region. A posterior gastrojejunostomy was done. After the operation the patient quickly gained weight but for several weeks he had a nutritional edema of the feet. On discharge, forty-three days after operation, his weight had increased 35 pounds, to 161 pounds.

*Diagnosis and Summary.*—Duodenal ulcer with pyloric stenosis. Emaciation due to nonutilization of the diet because of vomiting; nutritional edema. Recovery followed a gastrojejunostomy and adequate feeding.

**Case III.**—This man was referred for examination in June, 1935. He was thirty-six years of age, 70 inches tall, and weighed 126 pounds. Complaint was made of marked loss of

weight, exhaustion, ankle edema at night in the past six months, and diarrhea. Symptoms had been present for a year and a half, but he had continued his work as a bank manager. In October, 1933, he gradually lost his appetite and ascribed this to business worries. He vomited at irregular intervals and had occasional diarrhea. In May, 1934, a gastro-intestinal study led to a suspicion of duodenal ulcer; ulcer management gave only temporary relief. In January, 1935, he had from 2 to 6 urgent, watery, explosive stools daily. An Ewald meal showed no free hydrochloric acid, and the administration of hydrochloric acid, cod liver oil and liver capsules caused a temporary gain in weight. The diarrhea, however, continued and on admission to the hospital he had lost the weight previously gained.

Examination showed emaciation, scaphoid abdomen, and slight ankle edema. Blood pressure 100-68. Temperature normal. Teeth and tonsils showed no infection. Thyroid normal; heart and lungs normal; liver and spleen not palpable; no abdominal tenderness. Urine showed a trace of albumin, a few hyaline and occasional cellular casts. Wassermann negative. Blood count normal. Fractional test meal showed normal acid curve. Stools showed only a moderate number of fat globules; they were negative for amebae in fresh smears and in culture; stool cultures showed apparently normal bacterial flora. Proctoscopic examination was negative. Gastro-intestinal x-ray examination was negative save for a peculiar dilatation of the upper small intestine ascribed to atonicity; the colon was uniformly dilated to a moderate degree. Blood calcium 8.8 mg. per 100 cc. Basal metabolic rate — 16.6 per cent.

A balanced diet relatively high in protein content and low in fat was outlined; leafy vegetables and fruits were not restricted. A daily program insuring rest periods was planned. Liver extract was administered intramuscularly twice a week, and liver extract by mouth, calcium gluconate and viosterol were given. Improvement was rapid on this regimen. After four months the intramuscular injections of liver were discontinued. The patient now weighs 165 pounds and feels well. He has one or rarely two formed stools daily. He has had

several mild relapses when he has included much roughage in his diet and had loose stools with an upper respiratory infection.

*Diagnosis.*—Nontropical sprue, relieved by intramuscular injections of liver extract; inanition due to faulty utilization of diet as the result of diarrhea. Noteworthy findings were atonicity of the upper small bowel and the colon, a low basal metabolic rate and a slight hypocalcemia.

**Case IV.**—In this case emaciation was progressive for over ten months; cachexia was present for at least four months prior to death. The patient, a man forty-one years of age, developed painless jaundice after an attack of nausea and vomiting. After eight weeks an exploratory operation was advised and he entered a hospital. There was a delay of three weeks, after which he had a hemorrhage from the bowel. Several blood transfusions were given and finally three months after the onset of the jaundice, an operation was performed. Exploration was brief because of his poor condition. Gallbladder infection, a diffuse hepatitis and inflammation of the pancreas were reported. The gallbladder was drained. Drainage continued for three months, during which time he had 6 attacks of fever and chills. The jaundice finally cleared up and the patient was discharged in an emaciated state but feeling fairly fit. After a month at home he had an attack of vomiting and diarrhea followed by chills and fever. Slight fever continued thereafter.

Finally, about eight months after the initial jaundice, he was admitted to the hospital, cachectic, slightly jaundiced and with slight fever. Red blood corpuscles 3,560,000; hemoglobin 53 per cent. Stools contained bile pigment. A laparotomy had been planned for suspected biliary disease and subacute hepatitis, but the patient's condition scarcely warranted surgery. Signs of gastric retention appeared and a barium meal showed gastrectasis, believed due to duodenal obstruction. A laparotomy was performed but before satisfactory exploration could be carried out the blood pressure fell to a very low level

A jejunostomy was hurriedly done and a catheter implanted, the bowel being fixed to the abdominal wall. Jejunal feedings, averaging 1500 calories daily, were given by means of an automatic pump, and the stomach was aspirated through a nasal catheter. The patient lived for six weeks. Cachexia reached a maximum degree. Terminally, he became deeply jaundiced and developed ascites and edema of the legs. After abdominal paracentesis, a nodular liver was palpable. Necropsy showed a primary carcinoma of the ampulla with extension into the head of the pancreas; the liver was riddled with metastases; the common bile duct and the pancreatic duct were obstructed.

*Diagnosis.*—Carcinoma of the ampulla of Vater, with liver metastases; obstructing jaundice; progressive emaciation of ten months' duration. The prolonged clinical course strikingly emphasizes the fact that food will keep an individual alive indefinitely provided no complications occur. In this case jejunal feedings kept the patient alive for six weeks although emaciation was progressive because of carcinoma which prevented utilization of the nourishment supplied. Death finally occurred after a large percentage of liver tissue had been replaced by metastases.

**Case V.**—This patient, a married woman, twenty-six years of age, was apparently in good health in 1931, when she developed classical symptoms of diabetes. When she came to the hospital for treatment and instruction six weeks later she weighed 120 pounds. Her height was 64 $\frac{3}{4}$  inches. Physical examination was negative; the basal metabolic rate was normal.

Observation has been continued for almost five years. The diabetes has been fairly well controlled by means of insulin and a weighed diet providing 40 to 50 calories per kilogram of her present body weight of 116 pounds. There are, however, marked fluctuations in the fasting blood sugar level and there is occasional glycosuria. Emotional disturbances have been observed to produce hyperglycemia. On the other hand, severe hypoglycemic reactions have occurred after unaccustomed exercise and when meals have been delayed. The susceptibility

to reactions is ascribed to a low hepatic glycogen reserve. Undernutrition has persisted in spite of the provision of calories estimated as sufficient to produce a gain of weight under ordinary circumstances. The undernutrition is believed to be due in part to lack of utilization of the diet because of imperfect control of the diabetes and in part to an associated dysfunction, difficult to classify, of glands of internal secretion other than the pancreas.

*Diagnosis.*—Diabetes mellitus, severe; undernutrition, due in part to imperfect control of the diabetes but chiefly to the type of diabetes present.

**Case VI.**—This patient, a graduate nurse, was admitted to the hospital in 1932 because of weakness, loss of weight, tachycardia, dyspnea on exertion, and nervousness. She was thirty-eight years of age, 67½ inches tall, and weighed 117 pounds. Symptoms had been present for almost four years. In 1928, because of loss of weight, a basal metabolic rate determination was made and found to be +24 per cent. Hospitalization was refused at that time. She gradually lost 32 pounds in weight; her feet and ankles were frequently edematous after walking. Nausea and vomiting had occurred at intervals for a year.

Examination showed marked undernutrition, a small symmetrical goiter, slight exophthalmos, a pulse rate of 100, and a fine tremor of the fingers. A well compensated rheumatic heart lesion (mitral stenosis) was present and had been recognized when she began her hospital training. Basal metabolic rate was +40 per cent. After three weeks of bed rest, a high caloric diet and iodine therapy, her weight increased from 117 to 129 pounds, and the basal metabolic rate dropped from +40 to +17 per cent. A subtotal thyroidectomy was then performed. Sections of the gland showed hyperplastic goiter almost completely involuted by iodine therapy.

Recovery was prompt and complete. She has been able to continue nursing in the past four years. Her present weight is 150 pounds.

*Diagnosis.*—Exophthalmic goiter; inanition due primarily

to hyperthyroidism and secondarily to an inadequate diet; rheumatic heart disease, compensated and nonsymptomatic.

**Case VII.**—This patient, a druggist, thirty-nine years of age, weighs 117 pounds and is 70 inches tall. Fatigue and weakness began three years ago. In the past two years he has lost 35 pounds in weight. Stiffness of the back began two years ago; in the past year he has been unable to bend his spine and he has suffered pain after getting out of bed. For three months he has noted afternoon fever and he has had two or three watery bowel movements daily. There is no history of sweats or hemoptysis.

Examination shows emaciation. The spine is rigid. Thyroid normal. Heart normal save for a rate of 92 to 120. Blood pressure 106-74. The lungs show limited expansion, dullness, high-pitched expirations and râles in both apices. The abdomen is scaphoid, soft. Roentgen examination of the chest shows fibroid changes with cavitation in both apices. Gastro-intestinal x-ray study was negative save for a slight gastric residue eight hours after the barium meal and a colon almost empty after twenty-four hours. Roentgenograms of the spine show spondylitis deformans but no tuberculous caries. The sputum contained many tubercle bacilli; none could be found in the stools examined. The temperature is of septic type with an afternoon rise to 101° and 102° F. White blood corpuscles 19,800.

*Diagnosis.*—Inanition due to active, chronic pulmonary tuberculosis with cavitation; spondylitis deformans.

#### CLASSIFICATION OF INANITION

Brugsch,<sup>1</sup> in 1919, classified emaciation as due to: (1) deficient diet (complete inanition or starvation, and incomplete inanition from food intake, inadequate either as to quantity or quality); (2) increased metabolism, as hyperthyroidism; (3) infection, either acute or chronic; (4) progressive protoplasmic degeneration, as in carcinoma (cachexia); and (5) diseases of metabolism, as diabetes.

It seems evident that the mechanism of emaciation must be

either a deficiency in the intake of food or nonutilization of the diet, or excessive catabolic processes. On this basis, omitting from consideration physiological or constitutional leanness, which rarely produces symptoms, marked undernutrition may be classified as follows:

1. *Inadequate diet:*

- (a) Absolute starvation.
- (b) Undernutrition (semistarvation or incomplete inanition); diet deficient in calories or in essential "protective" constituents (protein, vitamins or minerals), or in both respects.

*Examples:* Habit, early satiety, dietary fads, unbalanced reduction diets, restriction as a result of previous symptoms or treatment; poverty; nervous or psychotic factors (psychogenic anorexia); therapeutic use of semistarvation as in recent treatment of chronic cardiac states.

2. *Faulty utilization of diet:*

- (a) Vomiting, nervous, cardiospasm, pyloric or intestinal stenosis; previous surgical anastomoses.
- (b) Imperfect mastication of food due to absence of teeth.
- (c) Diarrhea, due to sprue, ulcerative colitis, chronic dysentery, etc.
- (d) Absence of free hydrochloric acid; absence of bile in duodenum in jaundice; lack of digestive hormones in pancreatic disease; absence of antianemia substances; deficiency of pancreatic hormone in uncontrolled diabetes; impairment of hepatic function in liver disease.
- (e) Diffuse parenchymatous changes due to bacterial or other toxins; carcinoma.

3. *Excessive catabolism, as in:*

- (a) Hyperthyroidism.
- (b) Hyperparathyroidism.
- (c) Hypophysial cachexia (Simmonds' disease).
- (d) Fevers, acute and chronic.
- (e) Leukemias.
- (f) Malignant tumors.
- (g) Drugs, as desiccated thyroid gland and dinitrophenol.

Obviously, more than one mechanism may be concerned. For example, in fevers and in hyperthyroidism, anorexia may occur and result in a deficient food intake. In dinitrophenol therapy, in addition to increased metabolic activity there may occur dangerous toxic effects on various tissues.

## DISCUSSION

Emaciation, when present, is apparent on inspection of the patient. By comparing the weight with that of the average

for an individual of the same age, height and sex, one may calculate the percentage of underweight. Lesser degrees of undernutrition are frequently disregarded even though the realization is becoming widespread that dietary deficiencies are common and appear to be responsible for a large, varied group of disorders, often ill-defined, including latent scurvy, beriberi, and pellagra; edema; dermatoses; anemia; exhaustion; "gastro-intestinal invalidism" or vague ill-health. Many of these disorders occur despite a fair state of general nutrition and are corrected by insistence upon an adequate supply of the so-called "protective" foods.

An *evaluation of dietary habits* should be a part of every history whether a routine health examination is made or search is made for a pathologic basis of presenting symptoms. Inquiry as to whether the diet contains as a foundation the necessary protective substances (protein, minerals, vitamins) furnished by milk, eggs, leafy vegetables, fruits, meat or other foods of high protein content, and butter, surprisingly often finds a deficiency even in individuals who are apparently well. Since there is ample evidence that prolonged deficiencies may finally lead to severe manifestations, correction is a preventive measure of importance comparable to the correction of obesity after middle age.

In an undernourished individual the history often gives a definite clue as to the probable cause or causes. Many patients admit anorexia and a restricted diet. The symptoms described and the physical findings suggest the special examinations required to detect suspected or possible pathology. When organic disease has been ruled out, and frequently when organic disease is also present, it is necessary to prove and to demonstrate to the patient that his diet is, in fact, inadequate. To demonstrate this the patient must make a list of the items of food that he has actually consumed and the approximate amounts. From such a list one can calculate the approximate calories and reach a conclusion as to the qualitative adequacy of his diet.

The principles of *treatment* of inanition due entirely to a

deficient diet are obvious. The problem is to see to it that the patient actually follows a balanced diet of caloric content in excess of his activity requirements and that he continues on this diet. In practically every case in which uncontrollable systemic disease is absent, a gain in weight is possible provided the patient is cooperative and willing to make the necessary sacrifices. Since there are no practical clinical means of determining the total daily energy output, it is necessary merely to supply a caloric intake that is high and that evidently exceeds the caloric requirements. Execution of this program may, indeed, be difficult. The patient must be taught food values and a program of daily routine, and he must be guided and encouraged. Frequently an adequate diet adjusted to individual idiosyncrasies is prescribed, but one finds that the patient does not eat it. We must ask him to list what he has really eaten. A measured diet or, ideally, a weighed diet is preferable. In hospital management ingestion of the prescribed weighed diet is checked by weighing what is left on the patient's tray.

*Injections of insulin* before meals have been used with good results in many cases of undernutrition. There is, however, a real danger of serious hypoglycemic reactions in emaciated individuals who have little hepatic glycogen reserve. The threat of a reaction may be of definite psychic value in nervous patients who refuse to eat. This is probably the real value of insulin in most instances. Various concentrated preparations of *accessory food factors and minerals* that may be used to supplement the diet are available. Iron, in the form of ferrous sulphate or iron ammonium citrate, is of value since most patients with inanition are anemic; its use frequently causes improvement manifested by increased appetite. The calcium intake, chiefly provided by milk, may be augmented by the use of calcium gluconate, lactate or dicalcium phosphate. Liver extracts are of benefit in many instances and are available for oral or intramuscular use. In addition, vitamin D may be administered in concentrated form (viosterol) or may be furnished with vitamin A in cod liver oil or concentrates, or in

halibut liver oil. Vitamin B may be added by means of various wheat germ concentrates.

In cases of inanition due primarily to causes other than dietary deficiency, recognition of such cases is, of course, essential. Treatment can be successful only in so far as the pathology or dysfunction responsible can be removed, controlled or modified. Thus, mechanical obstruction can be removed; sprue treated with liver extract and diabetes with insulin; and hyperthyroidism decreased by iodine and abolished by thyroidectomy.

In all of these conditions, diet remains of great importance. In patients with nervous vomiting, fluids by any route and feedings by means of a duodenal tube or nasal catheter can be given. In exophthalmic or toxic goiter a high caloric diet enables the patient to gain weight as the hyperthyroidism is checked by iodine therapy, so that the patient approaches operation as a good surgical risk. In emaciation due to tuberculosis the patient's hope of recovery is largely dependent upon his ability to utilize a balanced, high caloric diet that enables him to gain weight, and that provides conditions favorable to healing of the tuberculous process. Even in carcinoma, if the patient can maintain his nutrition, his life can be prolonged until mechanical complications and metastases cause death.

### CONCLUSION

Inanition is a state of extreme undernutrition due to a quantity or quality of nourishment that is deficient for the individual. This deficiency may be due to a manifestly inadequate intake of food or may be relative, due to increased metabolic activity. In other instances the deficiency is due to faulty utilization of an average normal food intake.

Treatment depends on the recognition and relief or modification of any controllable functional or pathological condition that may be present and that prevents normal utilization of foodstuffs or increases metabolic activity. When this has been accomplished, in inanition due to disease as in emaciation due to inadequate diet, continued daily ingestion of a balanced diet

more than sufficient in caloric value to meet the energy requirements of the individual will result in appreciable gain in weight and relief of symptoms due to inanition.

## CLINIC OF DR. ARTHUR F. ABT

MICHAEL REESE HOSPITAL

---

### THE DIAGNOSIS OF LEUKEMIA IN CHILDHOOD

THE diagnosis of leukemia in infancy or childhood should offer no particular difficulty when one is confronted with a case presenting the classical symptoms and signs of this condition. However, a group of atypical cases, some nonleukemic in nature which have clinically resembled leukemia, and others of a true leukemic nature which have been mistaken for other diseases, often fail to make diagnosis simple and infallible. I wish to present, therefore, a group of cases which have been of interest and offered differential problems in personal experience.

The majority of leukemias in the young are of the acute type.<sup>1</sup> Chronic myeloid leukemia, while of infrequent occurrence, is an accepted and undisputed disease in childhood and the clinical condition is the same as in adult descriptions of the disease. Chronic lymphatic leukemia is said by many never to occur in childhood. There are some well authenticated reports which have recently been collected which make it seem probable that chronic lymphatic leukemia does occur in childhood, though it is certainly the least common type found in young life.<sup>2</sup> In this presentation, therefore, I shall limit myself to a discussion of the acute types of myeloid or lymphatic leukemia.

**Symptoms.**—The symptomatology of leukemia in young life may be very briefly reviewed. The onset is usually acute with fever, headache, loss of appetite, vomiting and asthenia. The initial symptoms are followed by increasing weakness, apathy, pallor, and abdominal or bone or joint pain. Of frequent occurrence are hemorrhages from the mucous membranes

or into the skin, cervical adenopathy, stomatitis, and occasionally nervous symptoms. Dyspnea and cough are noted in cases of mediastinal leukemic tumor. Submaxillary and lacrimal gland swellings are sometimes noted, as well as leukemic skin infiltrations. With the rapid development of anemia the skin becomes white or lemon colored. Leukemic infiltrations occasionally occur in the retina and also in the stomach. Infiltrations are more frequent in the intestinal tract, and, when ulcerative, may cause diarrhea. Metastatic infiltrations may cause tumor formation, as in chloroma.

From these symptoms it may be seen that leukemia may be mistaken for other conditions if a thorough blood examination is not made.<sup>8</sup> Such diseases as diphtheria, ulcerative stomatitis, angina, purpura, scurvy, and endocarditis may be suspected from the initial symptoms manifested in the mouth and throat and from the hemorrhagic tendency and the febrile course.

**Cytologic Differentiation.**—Leukemia may be suspected when leukocytosis or hyperleukocytosis is present, though it may be characterized by leukopenia throughout its course. Morphologic examination of the blood is necessary for a definite diagnosis. Predominance of immature forms of myelocytic or lymphatic type will differentiate myelogenous from lymphatic leukemia. Prevalence of immature cells and smudges aid in the diagnosis.

In mature types of cells the oxydase reaction is positive for the myelocytic type and negative for the lymphocytic type. However, younger myelocytic cells, as myeloblasts, are also oxydase-negative. Cases are reported in which monocytes were the predominant type of cell and these are considered by many to be a third type of leukemia known as monocytic leukemia.<sup>4</sup> These are believed by others to belong to the myeloid or the lymphatic types. *Stem-cell leukemia* is a term applied when very immature cells predominate.

Leukemia is most often associated with a leukocytosis, though it is becoming more generally recognized that many cases are characterized by a leukopenia throughout their course.

I have, therefore, divided the material to be presented into, first, a group where leukocytosis occurs and, second, into a group where leukopenia occurs.

#### GROUP I. DIFFERENTIATION WHEN LEUKOCYTOSIS IS PRESENT

##### (A) Nonleukemic conditions simulating leukemia:

1. Pertussis.
2. Pneumonia.
3. Sepsis.
4. Von Jaksch's pseudoleukemic anemia.
5. Cooley's Mediterranean erythroblastic anemia.
6. Infectious mononucleosis.
7. Mediastinal tumor.
8. Niemann-Pick essential lipoid histiocytosis.

##### (B) Leukemia simulating other conditions:

1. Simulating mediastinal tumor.
2. Simulating rheumatism.
3. Simulating diarrhea.
4. Simulating parotitis.

The following cases illustrate (A) of group I in the classification presented:

**Pertussis** is usually accompanied by leukocytosis and lymphocytosis. Not infrequently hyperleukocytosis of such a degree may be present that a diagnosis of leukemia may be suspected.<sup>5</sup> The following case is illustrative:

**Case I.**—A female infant seven months of age was brought to the hospital because she had had 4 convulsions during the previous night. A history of a cough of two weeks' duration which had gradually increased in severity was obtained. The infant had vomited several times for two days prior to admission; this was attributed by the mother to the coughing. The convulsive seizures had been of a definite clonic nature and were generalized. The infant had been a normal, full term delivery, breast fed, with no history of previous convulsions. The remainder of the history was irrelevant and there was no history of exposure to pertussis.

Physical examination revealed a fat, well-nourished seven-

month-old infant weighing 18 pounds, 14 ounces. The temperature on admission was 100.6° F. There was no cranio-tabes; the anterior fontanel admitted 2 fingertips; there were no enlarged bases and no enlargement of the costochondral junctions and no widening of the epiphyses. Otoscopic examination of the ears revealed pale, normal drums. There was harsh breathing, and a few moist sibilant râles were heard at the left base posteriorly. The breath sounds were vesicular throughout and there was no dulness or impairment of resonance. The heart was not enlarged to percussion, the tones were clear, and there were no murmurs. The abdomen and extremities were normal. The routine complete blood examination showed an amazingly high white blood count. The hemoglobin was 80 per cent (Sahli); red blood cell count 5,025,000; white blood cell count 213,000. The differential count showed polymorphonuclears 27 per cent, small lymphocytes

TABLE 1  
BLOOD FINDINGS IN A CASE OF PERTUSSIS

Day.	White blood count.	Polymorpho-nuclears.	Lymphocytes.		Transi-tional.	Eosino-phil.	Baso-phil.
			Small.	Large.			
First (ad-mission)	213,330	27	5	65	0	3	0
Second	115,600	35	8	56	0	1	0
Third	108,000	38	10	50	1	1	0
Fourth	95,000						
Fifth	88,000						
Sixth	86,500	37	42	18	1	2	0
Eighth	66,000						
Tenth	58,000	24	54	18	1	3	0
Twelfth	24,600						
Fifteenth	21,000	19	66	13	1	1	0

5 per cent, large lymphocytes 65 per cent, and eosinophils 3 per cent. The detailed blood examination is given in Table I.

**Pneumonia** is sometimes accompanied by high initial white blood counts.

**Case II.**—A four-year-old male child was taken sick with fever and slight cough. On initial examination some râles were heard over the right lower chest, and the spleen was palpable. Blood examination showed a white count of over 40,000 with 60 per cent large lymphocytes and mononuclear cells. Two days later the signs of a frank right lower lobular pneumonia were present. Recovery from the pneumonia was uneventful by lysis. There was a gradual drop in the white blood count and the differential count returned to normal on the tenth day.

We may consider the blood reaction in this child as of a lymphatic type. While lymphocytosis is physiologically present in the blood of younger children, still there is a type of child, known as the exudative lymphatic type, who will respond under slight or severe infections with a leukocytosis of lymphatic nature besides showing glandular enlargement and enlargement of the spleen.

Sepsis in infants and young children may show protean manifestations. A leukemia is often simulated when the focus of the infection is obscure, the onset sudden or insidious with fever, the spleen and lymph nodes enlarged, and when a progressively developing anemia with hemorrhagic manifestations and atypical blood findings occur. The correct clinical diagnosis of the following case was not made clear until the microscopic sections made during a careful pathologic study revealed the true nature of the disease.

**Case III.**—A five-year-old male was taken acutely ill with fever and abdominal pain. There was some abdominal muscle spasm. The white blood count showed 22,000 cells, 89 per cent of which were lymphocytes. Appendectomy was followed by pneumonia, following which the white count dropped. Recovery was never complete; the patient developed a stomatitis and febrile periods ensued. The stomatitis cleared and then recurred, accompanied by gingivitis, and an ulcerative lesion of the soft palate developed. Hemorrhages from the mucous membranes of the mouth and purpuric spots of the skin occurred and a dry gangrene of one finger tip was noted. The

Fig. 1.—Bone marrow from Case III; sepsis simulating leukemia. Showing clumps of cocci. ( $\times 390$ .)

Fig. 2.—Liver from Case III; sepsis simulating leukemia. Showing clumps of cocci. ( $\times 400$ .)

spleen was considerably enlarged and the liver palpable. The white blood count rose to 57,000 and finally dropped to 900. A lymphocytic preponderance was noted practically throughout the course of the disease. Autopsy showed an organizing bronchopneumonia with clumps of cocci disseminated in the bone marrow and liver (Figs. 1, 2). Careful examination of the spleen and lymph nodes revealed no trace of leukemic infiltration (Fig. 3). With the clinical course, signs and symp-

Fig. 3.—Section of lymph node from Case III; sepsis simulating leukemia. Showing no leukemic infiltration. Marked increase in plasma cells, characteristic of sepsis. ( $\times 400$ .)

oms. and the blood examinations, this case would have fitted perfectly into a diagnosis of acute lymphatic leukemia. The complete blood findings are given in Table 2.

Von Jaksch's anemia infantum, pseudoleukemia, occurs in infants from six months to two years of age.<sup>6</sup> It is characterized by a severe anemia, leukocytosis, and with many nucleated red blood cells and other immature cells in the circulating blood. An enlargement of the liver and spleen is

5/ 4/32	30	1,500,000	900	12	88	0	0

also present. The condition has been associated with rickets and infection, and is probably a severe form of secondary anemia due to the association of these two conditions.

**Case IV.**—The following case illustrates this condition. A thirty-month-old female infant was seen with the complaints

TABLE 3  
BLOOD FINDINGS IN A CASE OF JAKSCH'S ANEMIA

2/17	30	2,080,000	34,600	55	30	4	11	55

of vomiting, constipation, loss of weight, and pallor of one month duration. Examination revealed a pale, poorly nourished infant with a rachitic rosary and widening of the epiph-

yses. The liver and spleen were large. The temperature was of a subfebrile character and the Wassermann reaction was negative. The blood findings showed a leukocytosis with an increase in nucleated red blood cells, and a detailed examination of the blood is given in Table 3.

**Erythroblastic anemia** is a rare form of anemia first described and named by Cooley,<sup>7</sup> who differentiated it from Von Jaksch's anemia. It occurs in infants of families originating in Mediterranean countries and is of congenital, familial and racial incidence. It is a slowly progressing anemia characterized by large numbers of nucleated red cells in the peripheral blood. There is enlargement of the liver and spleen, a mongoloid facies, and a characteristic change in the bones on x-ray which show a thinning of the cortices and a widening of the medullary portion with prominent trabeculation and radiating spicules from the inner table of the skull.

**Case V.**—A Greek male infant, two and one-half years old, had been normal at birth. At eight months of age it was

12/8	25	1,100,000	10,200	55	43	0	2	0

noted that his abdomen became prominent. On examination he showed a marked pallor, his temperature was subfebrile

with an occasional sudden rise; his expression was dull with a wide flat nose and with his prominent abdomen he gave a somewhat mongoloid appearance. His liver was enlarged and his spleen extended nearly to the umbilicus. A detailed blood picture is given in Table 4.

**Acute infectious mononucleosis**, sometimes termed Pfeiffer's disease or glandular fever, is an acute illness with general glandular swelling, enlargement of the spleen and fever of long or short duration.<sup>8</sup> There is usually a reddening of the throat and at times follicular spots or a pseudomembranous type of angina are present. A leukocytosis is present and is manifested by an increased number of small and large lymphocytes and monocytes. The course of the disease is usually mild. Thoracic and abdominal symptoms may occur from enlargement of the lymph glands in these regions.

The resemblance at the onset to acute leukemia may be striking with the throat lesions, fever, glandular and splenic enlargement. However, the throat lesions are less extensive than in leukemia and clear up rapidly, the disease is generally less severe, and the anemia and hemorrhagic symptoms characteristic of leukemia are absent. Diagnosis from the blood picture alone is not always possible, though some authors maintain that the large lymphocytes and monocytes found in infectious mononucleosis are pathognomonic for this condition.

A diagnostic test for infectious mononucleosis has recently been reported. It has been found that heterophile antibodies demonstrable in the form of sheep-cell agglutinins have been recorded in high concentration in infectious mononucleosis. The existence of heterophile antibodies was first recognized by Forssman<sup>9</sup> and they have been investigated by numerous observers, particularly by Davidsohn<sup>10</sup> in recent times. It has been found that certain substances, such as emulsions of cells from the organs of various mammals, birds and fish, when injected into animals such as the rabbit, give rise not only to specific antibodies but also to nonspecific antibodies which may be demonstrated in the form of hemolysis and agglutinins for sheep cells. Davidsohn observed the presence of hetero-

phile antibodies in serum disease. Paul and Bunnell<sup>11</sup> were the first to show that heterophile antibodies in the form of sheep cell agglutinins were present in the serum of a patient suffering with infectious mononucleosis. They found that the antibodies were present in a much higher concentration in this condition than in the blood from serum disease or other conditions. Other investigators have since shown that this test for heterophile agglutinins for sheep cells is a valuable diagnostic procedure in differentiating infectious mononucleosis from other clinical conditions of a similar nature. Agglutination has occurred when the titer of the serum has ranged from 1:64 to 1:4096 in cases of infectious mononucleosis.<sup>12</sup> In serum disease the agglutination has been positive in dilutions as high as 1:64. In other conditions the highest titer for agglutination has been 1:8. It can, therefore, be said that cases presenting the clinical signs and symptoms of this disease with the accompanying blood picture whose blood serum shows an agglutination for sheep cells in a dilution of at least 1:64 can be diagnosed as infectious mononucleosis.

**Case VI.**—A four-and-one-half-year-old female child was taken acutely ill with fever, sore throat, vomiting and enlarged

cervical glands. The spleen was palpable 2 fingerbreadths below the costal margin. The acute illness was of four days' duration and the spleen was somewhat smaller after one week

and remained palpable for six weeks after the onset. The blood was marked by a leukocytosis with increase in the lymphocytes and mononuclear cells which were persistent for some time. There were no hemorrhages or petechial spots on the skin. The detailed blood examination is given in Table 5.

**Essential lipid histiocytosis (Niemann-Pick disease)** is a disease which occurs in infants under two years of age and is marked by mental and physical retardation, an early enlargement of the abdomen and enormous enlargement of liver and spleen.<sup>13</sup> Irregular fever occurs during the course of the disease. The blood findings are marked by slight to moderate anemia, leukocytosis with some increase in the mononuclear cells. Vacuolization of the lymphocytes and monocytes has been noted.

**Case VII.**—A female infant aged eight months complained of anorexia, irritability and protuberant abdomen for two months. The infant was pale and irritable, with a suggestive mongoloid appearance and gave signs of mental retardation.

TABLE 6

Postoperative	65	3,800,000	14,800	49	48	3	

The liver and spleen were greatly enlarged. The eyegrounds were normal and the serologic examination was negative. A splenectomy was performed and the typical foam cells were found in the spleen.

The detailed blood examination is given in Table 6.

The following cases illustrate (*B*) of Group I:

**Mediastinal enlargements** of the thymic area occur in leukemia.<sup>14</sup> This condition may be present before actual blood changes have occurred, and the symptoms from pressure on the trachea may cause dyspnea. Irradiation of the thorax will give relief in those cases where leukemic blood changes have not already occurred and the mass may completely recede, as shown by x-ray examinations. However, the condition is only temporary, as a leukemic blood picture and signs of a true leukemia develop after an interval.

**Case VIII.**—The case of a ten-year-old boy with a non-leukemic round-cell tumor of the mediastinum with a leukocytosis of 40,000 simulated this condition. The complaints were cough and a 7-pound loss of weight, shortness of breath, dyspnea and pain in the side present for one month. There was an inconstant fever, and the boy was thin and pale, showed immobility of the left chest, flatness over the left lung anteriorly and dulness posteriorly. Thoracentesis resulted in a dry tap. A laryngeal cough developed and death occurred suddenly.

TABLE 7  
BLOOD FINDINGS IN A CASE OF MEDIASTINAL TUMOR

Date	Hemoglobin	Red cells.	White cells.	Neutrophiles	Lymphocytes	Monocytes
5/13	75	4,160,000	15,000	46	44	10
6/7	65	3,800,000	40,000	52	40	8

Autopsy showed an infiltrative round-cell tumor of the anterior mediastinum invading the lung and pericardium. The blood findings are given in Table 7.

**Arthritis** may be associated with leukemia, with pains and swellings of the joints.<sup>15</sup> When the blood count is low, an acute rheumatic fever may be erroneously thought of.

**Case IX.**—A male, nine years of age, complained of swelling of the right elbow associated with fever. The child was

pale, thin and in considerable pain upon flexing his right arm. There was a considerable swelling of the right elbow, a general glandular enlargement, most marked in the cervical region; a palpable liver and an enlarged spleen. The temperature was 104° F. The white blood count was 10,450. The course of the disease was febrile; an increasing leukocytosis developed; swelling and redness of the left elbow occurred as well as of the metacarpals of the left hand. Finally the white blood count exceeded 40,000 and petechiae and hemorrhages occurred. Autopsy revealed the typical picture of an acute lymphatic leukemia.

The detailed blood findings are given in Table 8.

TABLE 8

BLOOD FINDINGS IN A CASE OF LEUKEMIA SIMULATING RHEUMATISM

6/5	40	2,400,000	94,000	0	91	0	9

Salivary gland enlargement may be associated with lymphatic leukemia. Mikulicz described a condition of chronic enlargement of the salivary and lacrimal glands, which was bilateral and painless, and which he believed due to a low grade infection. Cases of this type are known as Mikulicz's disease while those associated with other conditions have been termed Mikulicz's syndrome.<sup>10</sup> The relationship of mumps, syphilis and tuberculosis to this disease has been suggested.

**Case X.**—A nineteen-month-old infant was admitted with the complaint of bilateral swelling of the face for one month. He was well-nourished, slightly pale, with bilateral swelling of the submaxillary, parotid and lacrimal glands (Fig. 4). There was a general glandular enlargement. The white count on admission was 11,200, and this showed a decrease with a later

Fig. 4.—Nineteen-month-old infant with acute lymphatic leukemia, Case X. Showing swelling of submaxillary, parotid, and lacrimal glands, as well as enlargement of liver and spleen. Mikulicz's syndrome.

rise and terminal fall. The spleen was at first slightly palpable and later became greatly enlarged. During the last week of the disease the spleen rapidly shrank until it was barely palpable and the facial swellings receded. At autopsy the typical findings of acute lymphatic leukemia were demonstrated.

The detailed blood findings are given in Table 9.

The conditions above described were associated with *leukocytosis*. The following conditions are associated with *leukopenia*.

## GROUP II. DIFFERENTIATION WHEN LEUKOPENIA IS PRESENT

## (A) Nonleukemic conditions simulating leukemia:

1. Sepsis.
2. Agranulocytosis.
3. Gaucher's disease.
4. Nonlipoid splenohepatomegaly; Letterer-Siwe's disease.
5. Aplastic anemia.
6. Malaria.

## (B) Aleukemic leukemia simulating other conditions:

1. Simulating sepsis.
2. Simulating appendicitis.
3. Simulating aplastic anemia.

The following cases illustrate (A) of Group II in the classification.

**Sepsis** in infants and children may be marked by leukopenia, often of a severe degree. The disease may be manifested by hemorrhages, petechiae and enlargements of liver and spleen, and closely simulating leukemia.<sup>17</sup>

**Case XI.**—A female infant, nine months of age, presented the complaints of anemia and purpuric spots on the skin for six weeks. The infant was acutely ill, with marked pallor and a distended abdomen. The liver and spleen were both considerably enlarged. The blood findings showed a progressive anemia with leukopenia and a relative lymphocytosis. They are given in detail in Table 10.

TABLE 10  
BLOOD FINDINGS IN A CASE OF SEPSIS WITH LEUKOPENIA

Date.	Hemo- globin.	Red cells.	White cells.	Neutro- philes.	Lympho- cytes.	Undiffer- entiated mono- cytes.	Others
2/16	52	2,800,000	20,600	43	57	0	0
2/20	53	2,600,000	8,600	56	31	1	12 myelo- cytes.
3/10	40	1,900,000	4,000	0	70	30	0
3/15	30	900,000	3,600	0	65	35	0

**Agranulocytic angina**, or malignant neutropenia, is not so common in children as in adults<sup>18</sup>. The disease is characterized by an ulcerative nasopharyngitis, leukopenia and reduction or absence of granulocytes. Lymphocytes and monocytes are unchanged. The fundamental pathology occurs in the bone marrow. Causes of neutropenia are (1) shifting of neutrophils from the peripheral blood; (2) normal bone marrow, excessive destruction of neutrophils; (3) exhaustion or inability of bone marrow to produce neutrophils. The bone marrow is hyperplastic and microscopically shows decrease in activity of myelocytic cells. Many authors question the entity of this disease as described by Schultze, and prefer to consider the symptoms a syndrome which is capable of being produced by various etiologic agents.

**Gaucher's disease** is characterized by an insidious onset with the gradual enlargement of the spleen and later of the liver. Leukopenia is the characteristic blood finding with little change in the differential count. Hemorrhagic diathesis is

absent, and the course is protracted. Splenic puncture reveals typical Gaucher cells, pathognomonic for the disease.

**Letterer-Siwe's Disease. Nonlipoid Splenohepatomegaly, so-called "Reticulo-endotheliosis."**—I recently have encountered a very interesting case belonging to this group, which was mistaken clinically for aleukemic lymphatic leukemia.<sup>19a</sup>

This condition is characterized by a marked splenomegaly with moderate to considerable enlargement of the liver, a hemorrhagic tendency chiefly manifested as purpura, an involvement of the osseous system which may be manifested by tumor formation, or only may be recognized with the aid of the x-ray or, pathologically, a general enlargement of the lymph glands, and a blood picture which is characterized by a severe secondary anemia and slight leukocytosis to leukopenia.

The pathologic changes are characterized by a generalized hyperplasia and proliferation of the cells of the reticulo-endothelial system in various organs. The characteristic cells are large mononuclear cells, round or polygonal in shape, containing a nucleus poor in chromatin and a pale staining cytoplasm.

Splenic puncture may reveal an increased number of these typical pale staining cells of a nonlipoid nature so that a correct clinical diagnosis may be made. The course of the disease is gradually downhill, accompanied by fever of a continuous nature. The duration of the disease has varied from a few weeks to several years.

**Aplastic anemia** is a progressive anemia associated with splenomegaly, leukopenia and granulopenia and marked by a diminution of the granulocytic elements in the differential picture and a lack of regeneration of the red blood cells. The characteristic pathologic finding is a fatty or fibrous replacement of the bone marrow. The disease is probably a symptom-complex and may be caused by numerous etiologic factors. The condition can only be positively diagnosed by a pathologic examination of the bone marrow.

**Malaria**, while not often seen in temperate zones, may be confused with leukemia in regions where it is prevalent.<sup>19b</sup>

The splenomegaly with leukopenia may be mistaken for an aleukemic leukemia. There are cases reported in which malaria has complicated a leukemia. In chronic malaria the monocytes are often increased and occasionally a myelocytic increase may be noted. Where it is possible to demonstrate the malarial parasites in the blood the differential diagnosis should not be difficult.

The following cases illustrate (*B*) of Group II:

**Aleukemic leukemia** and sepsis with leukopenia are at times extremely difficult to differentiate. The following case is illustrative and proved at autopsy to be one of aleukemic lymphatic leukemia.

**Case XII.**—A seven-year-old female child complained of fever, vomiting, nose bleed and pallor of two weeks' duration.

Fig. 5—Microscopic section of liver from case of aleukemic lymphatic leukemia simulating sepsis. Case XII. Showing periportal leukemic infiltration of liver. ( $\times 650$ )

On admission the temperature was  $103^{\circ}$  F., there was some bleeding from the nose, and the spleen was slightly enlarged.

There was a marked anemia with leukopenia. Hemolytic streptococci were cultured from the blood. A diagnosis of sepsis was made and 5 transfusions were given at intervals. After six weeks the hemoglobin and red count were within normal values and the white count 7400. The child was afebrile and was discharged in excellent condition. Two weeks later she returned with a marked anemia and petechiae on the extremities. There was 32,800 white cells, of which 96 per

Fig. 6.—Microscopic section of kidney from case of aleukemic lymphatic leukemia simulating sepsis. Case XII. Showing leukemic infiltration. ( $\times 600$ .)

cent were lymphocytes. A septic course marked by angina and hemorrhages ended in death. The autopsy revealed the characteristic findings of lymphatic leukemia (Figs. 5, 6).

The detailed blood examinations are given in Table 11.

**Aleukemic leukemia** may simulate *appendicitis*. It will be noted that in a previous case here reported a child was operated for appendicitis and developed a sepsis simulating leukemia until autopsy proved the true condition.

10 17	46	2,800,000	5000	4	88	2	6

kocytes dropped and pentnucleotide was administered. There was a septic course with gradual decline. Liver and spleen were never palpable. At autopsy the diagnosis of lymphatic leukemia was established. The detailed blood examination is given in Table 12.

Aleukemic leukemia may simulate aplastic anemia and, as has been said, the diagnosis can only be definitely established by a pathologic examination of the bone marrow.<sup>20</sup>

The following unusual case which was under close observation for over two years showed an almost constant leukopenia accompanied by splenomegaly, anemia and lymphocytosis. The prolonged course and associated blood findings with neutropenia and the findings of myelocytes on only 2 occasions made a clinical diagnosis of aplastic anemia seem probable.

**Case XIV.**—A female child was first admitted at the age of four years with the complaints of weakness, loss of weight and night-sweats. The child was thin and pale with enlarged abdomen; anemia was marked. The liver and spleen were palpable. There were a few purpuric spots on the skin. Over a two-year period there were repeated exacerbations of fever, hemorrhages and enlargements of liver and spleen. During periods the symptoms subsided and the anemic condition improved. There were occasional complaints of pain over the long bones. Numerous transfusions were given during the course of the disease. Two months before the fatal termination blindness developed in the left eye. At times during the course of the disease the liver and spleen were barely palpable, while at other periods the enlargement reached to the umbilicus. Autopsy showed typical leukemic infiltrations of myeloid cells and the final diagnosis was chronic aleukemic myeloid leukemia. The detailed blood findings are given in Table 13.

**Leukemia in the Newborn Period.**—Leukemia may occur at a very early age. V. Kornmann<sup>21</sup> describes its occurrence in the newborn period in a six weeks' old female infant. Autopsy demonstrated that the case was one of acute myeloid leukemia of the myeloblastic type. In 1922 Koch<sup>22</sup> described this disease in 2 newborn infants. In 1924 Stransky<sup>23</sup> described myeloid leukemia in a three weeks' old female infant. In the same year Opitz<sup>24</sup> described the disease in a twelve weeks' old infant. Büngeler<sup>25</sup> in 1931 described congenital myeloid leukemia in a stillborn child. These 6 reports

12/ 9	20	900,000	3800	15	78	3	4	0

substantiate the occurrence of leukemia in the newborn period of life. Büngeler's case is of special interest as it occurred in a stillborn infant of seven months' gestation measuring 38 cm. in length and weighing 1620 Gm. Smears from blood of the vena cava and heart revealed 80 per cent myeloblasts and myelocytes. Many of these cells gave a positive oxydase reaction. There were many myeloid cells noted in the liver, spleen, myocardium, lungs, kidneys, and other organs. We may, therefore, be permitted to speak of a congenital type of leukemia. Baar and Stransky<sup>28</sup> quote several cases of congenital or newborn leukemia from the older literature and state that the existence of this condition has been proved beyond doubt. They further cite cases in which leukemic mothers have given birth to normal children. From the cases which

they cite they conclude that acute or chronic leukemia is not transmitted from mother to child.

There are several conditions occurring in the newborn which may be mistaken for leukemia. Under the term erythroblastosis of the newborn is now included the condition formerly known as icterus gravis neonatorum.<sup>27</sup> Newborn infants suffering from this condition either at birth or a few hours thereafter develop a rapidly deepening jaundice which is asso-

Fig. 7.—Schematic representation showing the potentialities for the development of granulocytes, normoblasts, macrophages and fibroblasts from hematocytoblasts and lymphocytes. (Maximow and Bloom's Textbook of Histology.)

ciated with anemia and a great number of immature erythrocytes in the circulating blood. Associated with the jaundice, anemia and erythroblastic blood picture are familial history, slight edema, extensive extramedullary hematopoietic foci in the liver and various organs with increased iron deposition and occasionally a nuclear icterus in the brain. The blood picture is characterized by a severe hyperchromic anemia with great numbers of immature red blood cells and occasional young white cell forms. Poikilocytosis, polychromatophilia with

stippling and increase in reticulated blood cells are noted. The icterus index is markedly increased and a biphasic van den Bergh reaction is present.

It might be easy in examination of the blood smear from such a case to mistake the nucleated red blood cells, some of which are present in a very early form, for leukocytes. Several investigators, in fact, have termed this condition fetal erythro-leukoblastosis and likened it to leukemia.<sup>25</sup> However, careful

Fig 8—Tissue culture from normal blood, showing development of macrophages and fibroblasts. (After Maximow, 1928.)

study of the pathologic histology has convincingly showed that erythroblastosis of the newborn is not related to leukemia. From present knowledge the cause of erythroblastosis of the newborn can best be ascribed to an embryonal persistence of hematopoiesis of erythrocytes in various organs.

Congenital syphilis may manifest itself by fever, purpura, enlargement of the liver and spleen, with anemia and occasionally with the presence of a great number of normoblasts

Fig. 9.—A stained smear from peripheral blood of a case of stem-cell leukemia.  
(After Timofejewsky and Benewolenskaja.)

Fig. 10.—Tissue culture from blood of patient shown in Fig. 9, showing growth of granulocytes and normoblasts. The stem cells from the original blood may now be identified as myeloblasts. (After Timofejewsky and Benewolenskaja.)

and a few immature myeloid cells in the blood stream.<sup>20</sup> If the typical luetic manifestations which accompany these phys-

ical and hematologic findings are recognized, the differentiation from leukemia should not be difficult.

**Tissue Culture of Blood.**—Since 1914 when it was first attempted, tissue cultures of leukemic blood have been made in attempts to differentiate and establish the origin of the cell types involved in the leukemias.<sup>30</sup>

In cultures of normal blood it has been found that macrophages and fibroblasts develop from lymphocytes and monocytes (Figs. 7, 8). In cultures of lymphatic leukemia the lymphocytes again develop into macrophages and fibroblasts.

On the other hand, in cultures of blood from myeloid leukemia the myeloblasts develop not only into macrophages and fibroblasts but also into myelocytes, granulocytes and normoblasts.<sup>31</sup> It is thus possible that by tissue culture we may be able to separate lymphoblasts from myeloblasts in cases of stem-cell leukemia where differentiation is otherwise impossible (Figs. 9, 10).

The following report may illustrate the value of tissue culture of the blood in determining the type of leukemia.

**Case XV.**—E. S., a thirteen-year-old girl, was taken ill with fever, epistaxis, bleeding from the gums, and purpura. Her spleen and liver were enlarged and there was general glandular enlargement. The child was acutely ill. Peripheral blood examination is given in Table 14.

TABLE 14

Date	Hemoglobin.	Red cells.	White cells.	Lymphocytes.		Oxydase reaction.
				Small.	Large.	
11 19	55	2,464,000	55,400	14	86	Entirely negative.
11 27			155,000	All lymphocytes.		Entirely negative.

Morphologically, we believed that we were dealing with an acute lymphatic leukemia. However, tissue cultures of the blood from this patient, at eighteen hours, contained at least 65 per cent myelocytes. We, therefore, had determined that

the cells in the peripheral blood which we took to be all lymphocytes and which were oxydase-negative, were in reality cells of the myeloid series, probably oxydase-negative myeloblasts. Instead of an acute lymphatic leukemia the case was really one of acute myeloblastic leukemia.

### CONCLUSIONS

A group of nonleukemic and leukemic cases are here discussed and illustrative examples presented to show how atypical cases of leukemia may be confused with nonleukemic conditions including those with leukocytosis and those with leukopenia. Cytologic as well as blood tissue culture methods of differentiation are briefly discussed. In some of these atypical cases clinical differentiation may be impossible. Sometimes even after the most careful pathologic review, the exact nature of the case may remain in doubt.

## CLINIC OF DR. HARRY L. HUBER

### UNIVERSITY OF CHICAGO MEDICAL CLINICS

---

#### FOOD ALLERGY

WHILE the old saying "what is one man's food is another man's poison" was trite long before the words "food allergy" were used, the clinical significance of the widespread sensitization to foods was not adequately recognized until allergists had demonstrated that in many cases of asthma and eczema (dermatitis) the symptoms were caused by commonly used foods. In the twenty-five years that have elapsed since the beginning of this work it has been shown repeatedly that a sensitization to a food or foods is the cause of symptoms in many cases of not only asthma and eczema, but also in many cases of urticaria (hives), migraine, and vasomotor rhinitis, and in some cases of arthritis, acne, epilepsy, certain gastro-intestinal disorders, agranulocytic angina, and intermittent hydrarthrosis. The relationship of food allergy to other types of clinical disorders is being studied and, without doubt, some of these will be added to the above list. The line of demarcation is as yet not clearly defined.

In the early days of this work tests were made with only a few of the most commonly used foods, but, as the work progressed, so many different foods were shown to be the cause of a certain clinical disorder in some patient that it is now safe to say that there is probably no article of diet to which some one is not sensitive. One must remember, too, that not only foods, but anything such as drugs, vaccine, mineral waters, etc., taken by mouth may be the etiologic agent.

The study of patients where food sensitization is suspected may be divided into four steps:

1. History taking.

2. Examination (physical and laboratory).
3. Correlation and summation of information (diagnosis).
4. Treatment.

The history must be taken in great detail. If questions are properly directed the patient is often able to give definite clues that lead to the discovery of the causative agent. The food likes and dislikes must be considered. The complexity of the modern diet makes it necessary for the physician to have a wide knowledge of foodstuffs. The hereditary history may also be significant. The time used in taking a history is well spent and often a diagnosis may be made when this is completed.

Complete physical and laboratory examinations should be made. Coexistent pathology, although not directly related, may interfere with the progress of the patient unless it is corrected. In addition to the usual routine laboratory examinations skin tests should be made with all known food contacts. These skin tests should be made first by the scratch method and then, if indicated, by the intradermal method. The technic of making these skin tests is described in most textbooks on allergic diseases. The following precautions should be observed:

1. Always do the scratch test before attempting the intradermal test with any food.
2. Do not make too many tests by any method at one time. Some testing materials are much more toxic than others and some patients react violently to several allergens.
3. Do not make tests with most drugs by either scratch or intradermal methods.

The testing materials should be obtained from a reliable source and should be fresh enough to insure their potency. If clinical tests with suspected foods are to be done at all, they should be made cautiously as serious reactions may occur. Although some patients may be found sensitive to only one specific food most of them exhibit multiple sensitizations. Sensitization to additional foods occurs easily after the initial sensitization has developed. The size of the skin reaction does

not necessarily indicate the degree of sensitiveness. The correct interpretation of skin reactions can be made only by correlating them with the data obtained from the patient's history. This information, together with that obtained from the history and the laboratory and physical examinations, should enable one to make a tentative diagnosis. If the patient's progress is not entirely satisfactory, additional helpful information may be obtained by rechecking the history and skin tests. In some cases in which the skin testing has not given helpful information trial elimination diets may be used successfully. The following cases demonstrate different types of food allergy.

**Case I. Asthma.**—Male, age sixteen. Complaint when first seen at age eleven: perennial asthma for two years. Previous illnesses: chickenpox at five, whooping cough at seven, measles at ten. No eczema at any time. Tonsils and adenoids removed at six. First attack of asthma came on after exposure to road dust in summer. Subsequent attacks came on at frequent intervals, summer and winter, with and without exposure to dust. Certain foods had been suspected and taken out of the diet with only partial relief. The usual laboratory and physical examinations revealed no significant pathology. Skin tests, made by the scratch method, showed distinctly positive reactions to duck feathers, goose feathers, cat hair, and to the following foods; oat, rice, wheat, navy bean, string bean, lettuce, onion, pea, radish, spinach, banana, blackberry, cherry, lemon, plum, rhubarb, and black pepper. Following this examination feather pillows were discarded and all the foods that gave distinctly positive reactions were eliminated from the diet. Within a week all symptoms of asthma disappeared entirely. About six months later light attacks of asthma began to appear, although the outlined program had been followed faithfully. Skin tests were repeated. Several of the foods that had previously given large reactions now gave only questionable reactions, but three, celery, white potato, and peach, that had previously given no reactions gave distinctly positive reactions at this time. These three foods were eliminated

from the diet and all symptoms of asthma again disappeared. Six months later skin tests were made with all the foods that had given positive reactions at any time and of these only four, banana, peach, pea, and spinach, remained distinctly positive. These four were omitted from the diet and the remainder occasionally eaten in small amounts only. About one year later symptoms of asthma again appeared but disappeared when the stricter diet was followed for a short time. During the next three years all foods excepting banana, pea, and spinach were gradually added to the diet without causing any symptoms. Skin tests now show positive reactions for only these three and they are still strictly avoided.

This case record illustrates the following common characteristics seen in food allergy:

1. Multiple sensitizations.
2. Disappearance of symptoms following the elimination of the sensitizing foods.
3. Recurrence of symptoms when the diet is not strictly followed and when sensitization to new foods occurs.
4. The persistence of some sensitization for several years.
5. The gradual disappearance of sensitizations following strict adherence to dietary restrictions.

**Case II. Pollen Disease and Asthma.**—Female, age thirty-one. Complaint when first seen at age twenty-seven: autumnal pollen disease and asthma. When this patient was eighteen years of age she had her first symptoms of autumnal pollen disease and two years later had her first asthmatic attack in the last week of that pollen season. The hay fever and asthmatic symptoms gradually became more severe each succeeding year. Skin tests were made with all the pollens common to the Chicago territory. She gave large positive reactions to the pollens of the large ragweed, small ragweed, and burweed marsh-elder, and treatments by injection were started with an extract made from these pollens. As she gave such large local reactions with each injection we could increase the size of the subsequent dose very little and, as a result, her maximum dose

was only a fraction of that given to the average patient. The results from this treatment were not entirely satisfactory. The next season the treatments were started in April in an effort to increase the dose to a higher concentration of extract. Although a much higher dosage was reached this patient had much hay fever and asthma in September. The next spring skin tests were made with all common foods and other contacts. Corn, rye, banana, pineapple, asparagus, kidney bean, cabbage, and cottonseed gave distinctly positive reactions. Pollen extracts were again given as in the preceding year and in addition all the foods that gave positive reactions were eliminated from the diet three weeks before the onset of the pollen season in mid-August and this modified diet was continued until October 1st, the end of the pollen season. Although this patient remained in the same environment as in the previous years she had no clinical symptoms of hay fever or asthma. This was the first season of comfort since her symptoms started twelve years before. In this case the foods to which she was sensitive plus the inhaled pollen caused her to have symptoms in spite of adequate pollen therapy, and satisfactory clinical results from pollen therapy could not be obtained until the toxic foods were eliminated. During the past season the same program has been followed with completely satisfactory results.

This case record illustrates a very common complication of pollen disease (hay fever). In some cases the patients themselves have discovered that their symptoms from pollens are worse after eating some common food such as peaches or cantaloupe, but in most cases the relationship of foods to the symptoms has not been suspected. In some allergy clinics complete skin tests are routinely made in all cases of seasonal and perennial rhinitis. Complete skin tests should be made at least in all those patients who have not responded satisfactorily to adequate pollen therapy.

**Case III. Migraine and Pollen Disease.**—Female, age forty-two. Complaints when first seen at age thirty-six: mi-

from the diet and all symptoms of asthma again disappeared. Six months later skin tests were made with all the foods that had given positive reactions at any time and of these only four, banana, peach, pea, and spinach, remained distinctly positive. These four were omitted from the diet and the remainder occasionally eaten in small amounts only. About one year later symptoms of asthma again appeared but disappeared when the stricter diet was followed for a short time. During the next three years all foods excepting banana, pea, and spinach were gradually added to the diet without causing any symptoms. Skin tests now show positive reactions for only these three and they are still strictly avoided.

This case record illustrates the following common characteristics seen in food allergy:

1. Multiple sensitizations.
2. Disappearance of symptoms following the elimination of the sensitizing foods.
3. Recurrence of symptoms when the diet is not strictly followed and when sensitization to new foods occurs.
4. The persistence of some sensitization for several years.
5. The gradual disappearance of sensitizations following strict adherence to dietary restrictions.

**Case II. Pollen Disease and Asthma.**—Female, age thirty-one. Complaint when first seen at age twenty-seven: autumnal pollen disease and asthma. When this patient was eighteen years of age she had her first symptoms of autumnal pollen disease and two years later had her first asthmatic attack in the last week of that pollen season. The hay fever and asthmatic symptoms gradually became more severe each succeeding year. Skin tests were made with all the pollens common to the Chicago territory. She gave large positive reactions to the pollens of the large ragweed, small ragweed, and burweed marsh-elder, and treatments by injection were started with an extract made from these pollens. As she gave such large local reactions with each injection we could increase the size of the subsequent dose very little and, as a result, her maximum dose

was only a fraction of that given to the average patient. The results from this treatment were not entirely satisfactory. The next season the treatments were started in April in an effort to increase the dose to a higher concentration of extract. Although a much higher dosage was reached this patient had much hay fever and asthma in September. The next spring skin tests were made with all common foods and other contacts. Corn, rye, banana, pineapple, asparagus, kidney bean, cabbage, and cottonseed gave distinctly positive reactions. Pollen extracts were again given as in the preceding year and in addition all the foods that gave positive reactions were eliminated from the diet three weeks before the onset of the pollen season in mid-August and this modified diet was continued until October 1st, the end of the pollen season. Although this patient remained in the same environment as in the previous years she had no clinical symptoms of hay fever or asthma. This was the first season of comfort since her symptoms started twelve years before. In this case the foods to which she was sensitive plus the inhaled pollen caused her to have symptoms in spite of adequate pollen therapy, and satisfactory clinical results from pollen therapy could not be obtained until the toxic foods were eliminated. During the past season the same program has been followed with completely satisfactory results.

This case record illustrates a very common complication of pollen disease (hay fever). In some cases the patients themselves have discovered that their symptoms from pollens are worse after eating some common food such as peaches or cantaloupe, but in most cases the relationship of foods to the symptoms has not been suspected. In some allergy clinics complete skin tests are routinely made in all cases of seasonal and perennial rhinitis. Complete skin tests should be made at least in all those patients who have not responded satisfactorily to adequate pollen therapy.

**Case III. Migraine and Pollen Disease.**—Female, age forty-two. Complaints when first seen at age thirty-six: mi-

graine since eighteenth year, grass pollen disease (rose fever) since eighteenth year. Attacks of migraine came at irregular intervals two or three times each month, summer and winter. Heredity: One half-uncle had hay fever and maternal grandfather had asthmatic bronchitis. Additional history not significant. Physical examination revealed no significant pathology. Skin tests made with all common foods, inhalants and other contacts gave positive reactions with all common grass pollens, and with one food, rye. The relationship of the ingestion of rye foods to the attacks of migraine had not been suspected as more or less rye bread was regularly used. However, this patient had observed that her attacks were always more severe while visiting a certain section of Canada and subsequent investigation showed that rye foods were extensively used there. Treatments were given with a grass pollen extract and all rye foods were eliminated from the diet. This patient has now been under treatment for six years and has had no symptoms of pollen disease and only an occasional attack of migraine when some rye food was knowingly or unknowingly eaten.

**Case IV. Urticaria and Asthma.**—Male, age fifty-seven. Complaint when first seen at age fifty-six: sudden severe attacks of abdominal pain, urticaria and asthma. For several years this patient has occasionally had severe abdominal pains which appear within one hour after eating and persist for one to two hours. Two or three of the more recent attacks have been accompanied by urticarial swelling of the face and trunk, nausea, vomiting, diarrhea and collapse. Except for these acute attacks this patient has been well. Skin tests made with all common foods, inhalants and other contacts gave typical positive reactions to sweetbreads, halibut, artichoke, paprika, and banana. The skin reaction to banana was very large and the patient admitted that he was fond of this food and frequently ate it liberally. Subsequently he exhibited a most severe attack after eating a portion of a banana. By eliminating all of these foods from the diet this patient was able to avoid the severe symptoms which frequently incapacitated him.

This case record illustrates some of the various symptoms which may follow the ingestion of some food to which one has become sensitized. In most cases of such sensitization the type of response is usually limited to one symptom, such as asthma, dermatitis, urticaria, migraine, etc., but in some cases two or more such symptoms appear in the same patient concurrently or alternately. In this case the sensitization to a food that had been eaten liberally since boyhood days did not occur until after middle life. Most sensitizations occur in the first decade of life.

**Case V. Asthma.**—Female, age thirty-eight. First seen at age thirty-seven with asthma. When this patient was thirty years of age she had her first attack of asthma following a severe chest cold. Following that attack she always had a few days of asthma with each fresh cold and after three or four years had frequent attacks in both winter and summer. She had learned from experience that she could precipitate a severe attack of asthma by taking acetosalicylic acid (aspirin) and would not use this drug knowingly. At the time of her admission skin tests made with all common foods, inhalants and other contacts gave reactions only to duck and goose feathers. Laboratory and physical examinations were made and no pathology was found except for evidences of infection in the sinuses and bronchi. Following the removal of feathers and the institution of conservative sinus treatments her symptoms became less troublesome but each fresh cold precipitated severe attacks of asthma. In the early stages of one of these colds she was advised by a friend to use one of the commonly advertised cold remedies. Within thirty minutes after taking the first dose she had such a severe attack of asthma that for hours her death seemed imminent. Investigation disclosed that the dose of cold remedy that she had taken contained about 2 grains of acetosalicylic acid. This case is cited to show that other things than foods taken by mouth may be the cause of asthmatic attacks. It is well to remember that several commonly used drugs may precipitate attacks of asthma or urti-

caria in those who are sensitized to them. The salicylates are the most common offenders and, as they are used in so many prescribed and proprietary medications, they should always be kept in mind when one is investigating an allergic patient. Quinine is probably the second worst offender.

**Case VI. Dermatitis.**—Male, age twenty-eight. When first seen at age twenty-six the complaint was dermatitis of the hands and face. This dermatitis first appeared when the patient was fifteen years of age and has been present more or less constantly since. He had worked at times in a bakery and thought that his lesions were more troublesome at such times, but they were present when he had no such exposure. Skin tests made with all common foods and other contacts gave distinctly positive reactions to corn, rye and wheat. These foods were eliminated from the diet and he avoided exposure by contact. The lesions gradually disappeared but would reappear if he ate cereal foods for two or three days in succession. For the past year he has been able to eat moderately of thoroughly toasted bread without causing any symptoms. In children and especially in infants cereal foods are more often found to be a cause of dermatitis than any other food. Citrus fruits are frequently the etiologic irritant in infantile dermatitis. Many bakers have dermatitis or asthma due to the ingestion, handling, or inhalation of cereal flours.

The most satisfactory method of desensitizing a patient to a food which has been shown to cause symptoms is the complete elimination of that food from the patient's diet. In some cases satisfactory desensitization may be accomplished in a few weeks while in others elimination of the food for years is necessary. Desensitization to eggs, for instance, usually requires a complete elimination of that food for years. In some cases of food allergy in children it may be necessary to eliminate the food from the home as traces of it may accidentally reach the patient. There are some who advocate desensitization in children by feeding small doses of a dilute solution of the food and increasing the strength gradually. This method has its limita-

tions and has not produced as satisfactory results as the complete elimination method.

Attempts have been made to desensitize by injecting an extract of the food subcutaneously but this method has not given satisfactory results. No attempts should ever be made to desensitize with drugs by the injection method.

In this discussion I have attempted to point out some of the salient features in the study of patients suspected of being allergic to foods. As has been stated the symptoms may be so varied and the causative agents so numerous that the relationship of the causative agent to the symptoms can be established only after a detailed study. The difficulties are greatest in those cases where multiple sensitizations are present or where there is an opportunity for exposure to unusual ingestants. In the daily life of the average inhabitant of a modern city there is a chance for exposure to about 150 different foodstuffs and in some cases the exposures are much above that number. In some special food mixtures there may be 10 or more individual foods. The discovery of the offending foods often enables the victim to change from a life of semi-invalidism to that of a comfortable self-supporting citizen. The time spent in solving problems of this sort pays comparable dividends.

CLINIC OF DRS. SAMUEL J. TAUB AND  
TOWNSEND B. FRIEDMAN

MICHAEL REESE HOSPITAL

POLLINOSIS

**Historical.**—That hay fever is due to sensitization to pollens is not a new discovery. A very accurate description of the symptoms was written by Bostock in England in 1819. in an article entitled "A Case of Periodical Affection of the Eyes and Chest," published in the *Medico-Chirurgical Transactions of London*. John Elliotson, another Englishman, was probably the first to record pollen as the probable cause of hay fever in 1836. In 1873, Blackley undertook very accurate experiments to identify the grass pollens as a cause of hay fever. He undoubtedly was the first to make use of cutaneous reactions. Among the earlier students of this problem in the United States, mention should be made of Morrill Wyman, who in 1876 wrote a monograph on "Autumnal Catarrh" in which he accurately describes fall hay fever and ascribes its cause to the pollen of ragweed.

**Etiology.**—What is referred to in medical terminology today as seasonal pollinosis is known to the laity as "rose cold" or "rose fever," for the very obvious reason that the symptoms coincide with the blooming of the roses, or it may be referred to as "hay fever," if the symptoms happen to coincide with haying time.

The causative agent of all seasonal pollinosis is pollen, which is a light yellowish granular powder, the individual granules of which are microscopic in size, produced in the reproductive cycle of the causative plant whether it be a tree,

grass, or weed. It is rather obvious that this pollen must be light enough to be air borne in order that it may gain entrance through the respiratory tract.

**Quantity.**—The pollinating seasons of the various plants in this locality have been determined by field surveys and pollen counts. These pollinating seasons are given in the tables below. These tables are applicable to Chicago and its immediate environs. Similar surveys have been made for practically all areas in the United States and can be found in any standard text on allergic diseases.

### TREES

Common name.	Pollinating season.
(Major)	
1. Oak.....	May
2. Cottonwood.....	March to April
3. Ash.....	April to May
4. Maple.....	February to March
5. Elm.....	March
(Minor)	
1. Box elder.....	April
2. Walnut.....	May
3. Hickory.....	May
4. Sycamore.....	April to May
5. Tree of heaven.....	June

### GRASSES

Common name.	Pollinating season.
(Major)	
1. Bluegrass.....	May to June
2. Timothy.....	June to July
3. Orchard grass.....	May to June
4. Red top.....	June to July
5. Canada bluegrass.....	June to July
(Minor)	
1. Quack grass.....	June
2. Sweet vernal grass.....	May to June

### WEEDS

Common name.	Pollinating season.
(Major)	
1. Short ragweed .. . . .	August to September
2. Giant ragweed.....	August to September
3. Burweed marsh-elder.....	August to September

WEEDS (Continued)

Common name.	Pollinating season.
(Minor)	
1. Cocklebur.....	August to September
2. Lamb's quarters.....	July to September
3. Pigweed.....	July to September
4. Western water hemp.....	July to September
5. Russian thistle.....	July to September
6. English plantain.....	June to July
7. Tall wormwood.....	August to September

**Diagnosis.**—One of the most important steps in arriving at an accurate diagnosis of seasonal pollinosis is obviously an accurate history containing the date and place of the onset of the first symptoms. One should always inquire for dates and these may be most easily secured by asking the patient, "Did you have symptoms on Decoration Day or Fourth of July or Labor Day?" Or one may inquire where and when the patient was on his last summer vacation. Also, one should inquire as to the organs involved. Do the eyes itch, was there excessive lacrimation, was there itching of the nose, ears, or palate? How many handkerchiefs did you use? What was the character of the nasal secretion? Was it watery or mucoid, was it white or yellow? Do you suffer with tightness or wheezing in the chest? How many years did you have hay fever before asthma developed?

Now that we have established a definite season we must determine the causative factor or factors. This we do by testing with either dry pollens or extracts of the various trees, grasses and weeds which bloom during the period that the patient has symptoms.

**Methods of Testing.**—1. *Scratch or Cutaneous Method.*  
—To perform the cutaneous test for the sensitivity to pollen, small scratches are made, usually on the flexor surface of the forearm or on the back in the paravertebral region. These scratches do not have to be deep, but merely should break the continuity of the epithelium. When dry pollen is used, a drop of  $\frac{N}{100}$  sodium hydrate solution is placed on each scratch and then a small amount of dry pollen is added to each drop. These

tests can usually be read in from ten to fifteen minutes. A more convenient method for the scratch test is to apply drops of 1:50 pollen solution to these scratches. A positive reaction usually manifests itself by the formation of a wheal with a surrounding area of erythema.

While this method is a great aid in diagnosis of pollinosis in many patients, were we to depend upon it entirely, many diagnoses would be missed, as it is not an uncommon occurrence to find a patient who reacts not at all by the scratch technic but who still gives large reactions when tested by the intracutaneous method.

2. *Intracutaneous Method.*—With the intracutaneous method of testing we use a 1:1000 solution of the pollen and the test is performed with the aid of a tuberculin syringe and a 26-gauge short bevel needle. The site for the test which has been found most favorable is the extensor aspect of the upper arm. A very small amount of the test solution is injected intracutaneously and we do not attempt to measure this amount, but are guided by the small wheal which it raises and which is usually about 1 or 2 mm. in diameter. Occasionally a patient will not give positive reactions with a 1:1000 solution and we then test with a 1:500 solution, and if this proves negative we also test with 1:100.

3. *Conjunctival Test.*—If all these tests are negative and we still suspect pollen disease, we may perform the conjunctival test which consists of placing a small amount of dry pollen in the conjunctival sac and observing whether or not it produces a marked injection of both the palpebral and bulbar conjunctiva.

4. *Subcutaneous Injection Test.*—Another method of testing that has been used for patients refractory to cutaneous testing is the subcutaneous injection method where one injects a small amount of a more concentrated solution, 1:500 or 1:100, subcutaneously, and observes the patient for a systemic reaction manifesting itself either as hay fever, urticaria, or asthma, and also observing the site of the injection for a large local reaction.

tests can usually be read in from ten to fifteen minutes. A more convenient method for the scratch test is to apply drops of 1:50 pollen solution to these scratches. A positive reaction usually manifests itself by the formation of a wheal with a surrounding area of erythema.

While this method is a great aid in diagnosis of pollinosis in many patients, were we to depend upon it entirely, many diagnoses would be missed, as it is not an uncommon occurrence to find a patient who reacts not at all by the scratch technic but who still gives large reactions when tested by the intracutaneous method.

2. *Intracutaneous Method.*—With the intracutaneous method of testing we use a 1:1000 solution of the pollen and the test is performed with the aid of a tuberculin syringe and a 26-gauge short bevel needle. The site for the test which has been found most favorable is the extensor aspect of the upper arm. A very small amount of the test solution is injected intracutaneously and we do not attempt to measure this amount, but are guided by the small wheal which it raises and which is usually about 1 or 2 mm. in diameter. Occasionally a patient will not give positive reactions with a 1:1000 solution and we then test with a 1:500 solution, and if this proves negative we also test with 1:100.

3. *Conjunctival Test.*—If all these tests are negative and we still suspect pollen disease, we may perform the conjunctival test which consists of placing a small amount of dry pollen in the conjunctival sac and observing whether or not it produces a marked injection of both the palpebral and bulbar conjunctiva.

4. *Subcutaneous Injection Test.*—Another method of testing that has been used for patients refractory to cutaneous testing is the subcutaneous injection method where one injects a small amount of a more concentrated solution, 1:500 or 1:100, subcutaneously, and observes the patient for a systemic reaction manifesting itself either as hay fever, urticaria, or asthma, and also observing the site of the injection for a large local reaction.

we deem it advisable completely to test all patients suffering with pollinosis. Only rarely does one find a patient sensitive to pollen only.

2. Inadequate treatment, that is, the patient reports too late for the dosage to be raised to an effective therapeutic level. or the treatment is stopped too soon.

3. The extracts used in the treatment may have lost their potency.

4. The treatment antigen may not contain the pollens to which the patient is sensitive.

**Symptomatic Treatment of Hay Fever.**—When the patient presents himself with symptoms of hay fever the following local measures in addition to the injections will give some additional relief. However, a word of warning regarding drugs in the allergic patient is not amiss. Before any drug is prescribed the patient should be questioned as to any known drug sensitivity. For the eye symptoms the following drops used in the eyes every two to three hours will allay the itching and relieve the inflammation.

R Epinephrine chloride 1:1000	.....	℥ x
Dilute acetic acid	.....	℥ iii
Resorcin	.....	gr. ii
Aqua dest ad	.....	℥ i

Many patients get adequate relief of their ophthalmic symptoms from the simple use of the eye cup with dilute boric acid solution or the solution of oxycyanide of mercury 1:5000.

For excessive nasal symptoms we use a 1 per cent aqueous solution of ephedrine hydrochloride as a spray every two to three hours. We have found that oily solutions are too irritating to the sensitive mucosa. For those patients who cannot tolerate ephedrine solution we use one of the ephedrine-like synthetic preparations. If the obstruction to nasal breathing is very marked, nasal packs with a good vasoconstrictor produce considerable relief. By mouth, ephedrine  $\frac{3}{8}$  grain combined with amytal sodium  $\frac{3}{4}$  grain or phenobarbital  $\frac{1}{4}$  grain, given in capsules every four hours, relieves the sneezing and nasal congestion.

The dosage is increased according to the following schedule which we have found most useful in that the volume of the individual doses is small. It must be realized that this schedule is very flexible and is modified for each patient.

DOSE SCHEDULE

Concentration 1 : 50,000	Concentration 1 : 5000	Concentration 1 : 500	Concentration 1 : 50
Dose No. 1—0.05 cc.	Dose No. 6—0.05 cc.	Dose No. 11—0.05 cc.	Dose No. 16—0.05 cc.
Dose No. 2—0.1 cc.	Dose No. 7—0.1 cc.	Dose No. 12—0.1 cc.	Dose No. 17—0.1 cc.
Dose No. 3—0.2 cc.	Dose No. 8—0.2 cc.	Dose No. 13—0.2 cc.	Dose No. 18—0.2 cc.
Dose No. 4—0.3 cc.	Dose No. 9—0.3 cc.	Dose No. 14—0.3 cc.	Dose No. 19—0.3 cc.
Dose No. 5—0.4 cc.	Dose No. 10—0.4 cc.	Dose No. 15—0.4 cc.	Dose No. 20—0.4 cc. etc.

The peak dosage in our clinic is the highest dose which the individual patient will tolerate. There is no fixed rule as to what this dose is and it is best determined by the physician who is treating the patient. However, we do not increase the dose beyond that which gives the patient the optimum of relief. This treatment just described is termed the preseasonal and coseasonal method because the patient begins his treatment twelve to fifteen weeks before the beginning of his particular pollen season. When a subpeak dose is administered at bi-weekly intervals throughout the year, and then gradually increased again preseasonally, it is termed the perennial form of treatment. The two-week interval is to be preferred because on this schedule constitutional reactions are less likely to occur. Constitutional reactions are controlled by the administration of epinephrine chloride in doses of from 0.5 to 1 cc., administered by hypodermic injection.

*Causes of Failure.*—The causes of failure in the treatment of seasonal pollinosis are:

1. Incomplete or inadequate testing, as the patient may be sensitive to foods or common inhalants such as orris root, feathers, cottonseed, insecticides, or animal emanations in addition to the pollen sensitivity. Therefore, to obviate this cause

we deem it advisable completely to test all patients suffering with pollinosis. Only rarely does one find a patient sensitive to pollen only.

2. Inadequate treatment, that is, the patient reports too late for the dosage to be raised to an effective therapeutic level. or the treatment is stopped too soon.

3. The extracts used in the treatment may have lost their potency.

4. The treatment antigen may not contain the pollens to which the patient is sensitive.

**Symptomatic Treatment of Hay Fever.**—When the patient presents himself with symptoms of hay fever the following local measures in addition to the injections will give some additional relief. However, a word of warning regarding drugs in the allergic patient is not amiss. Before any drug is prescribed the patient should be questioned as to any known drug sensitivity. For the eye symptoms the following drops used in the eyes every two to three hours will allay the itching and relieve the inflammation.

R Epinephrine chloride 1:1000	.....	℥ x
Dilute acetic acid	.....	℥ iii
Resorcin	.....	gr. ii
Aqua dest ad	.....	℥ i

Many patients get adequate relief of their ophthalmic symptoms from the simple use of the eye cup with dilute boric acid solution or the solution of oxycyanide of mercury 1:5000.

For excessive nasal symptoms we use a 1 per cent aqueous solution of ephedrine hydrochloride as a spray every two to three hours. We have found that oily solutions are too irritating to the sensitive mucosa. For those patients who cannot tolerate ephedrine solution we use one of the ephedrine-like synthetic preparations. If the obstruction to nasal breathing is very marked, nasal packs with a good vasoconstrictor produce considerable relief. By mouth, ephedrine  $\frac{3}{8}$  grain combined with amytal sodium  $\frac{3}{4}$  grain or phenobarbital  $\frac{1}{4}$  grain, given in capsules every four hours, relieves the sneezing and nasal congestion.

For children from eight to twelve years of age the following prescription may be used:

Ephedrine HCl	...	gr. x
Elix. amytal	...	5 ss
Elix. lactopeptin	...	q.s. ad 5 iv

Sig.—1 teaspoonful every four hours.

Aspirin or combinations of aspirin with amidopyrine very often are helpful in allaying severe sneezing and nasal stoppage. If asthma complicates the hay fever symptoms, epinephrine chloride 1:1000 hypodermically in doses of 0.3 to 0.5 cc. repeated as necessary gives relief. Large doses of 1 cc. should not be used because of the toxic symptoms they produce such as tachycardia, pallor, fainting, vomiting and other symptoms of collapse.

Theophylline ethanol amine in capsules of 3 grains every three to four hours also has been found useful in asthma complicating hay fever.

Epinephrine 1:100 by inhalation has been disappointing in relieving asthma and we have discontinued its use.

The use of calcium, iodides, atropine and morphine for the relief of hay fever is mentioned only to condemn their use.

From the results we have seen, nasal ionization is apparently of no benefit in pollinosis. The same effect may be obtained with any escharotic such as 95 per cent phenol, strong silver nitrate, or the use of the actual cautery. Following ionization for pollinosis we have seen anosmia and neuritis of the nasal ganglion with severe pain following. We have also seen hyperesthesia of the sense of smell following its use. The use of nasal ionization should be discontinued in pollinosis. Pollinosis is a constitutional disease and should be treated as such. Any such severe local treatment to the sensitive nasal mucosa does more harm than good.

General measures such as avoidance of dust, swimming, exposure to the sun, heat and fatigue, golf and long automobile rides through the country should be followed. The diet should be carefully watched and all food allergens eliminated and the avoidance of all environmental factors such as orris root,

feathers, and other animal emanations should be carefully checked.

**Complications and Sequelae.**—The most common complication of hay fever which we see is pollen asthma. The usual history of this is that the patient has had pollen hay fever for several years and then suddenly developed pollen asthma. Usually the history is that two to three weeks after the onset of the hay fever in a certain year the asthma appeared. Occasionally we see the converse of this, in that the patient may have had pollen asthma for many years without ever having had any symptoms of hay fever. Obviously, the treatment of this pollen asthma is exactly that of pollen hay fever.

Another complication of pollen hay fever is pollen dermatitis. This may be either directly the result of sensitization to the pollen or it may be an old atopic dermatitis due originally to some other sensitivity but which has reappeared, apparently due to the pollen on either a specific or nonspecific basis.

Not uncommonly, there is a secondary infection superimposed on the pollen sensitivity resulting in a purulent sinusitis which may disappear at the end of the hay fever season or which may continue and become a most troublesome chronic affair. Commonly we see patients who at the beginning had only seasonal hay fever but who gradually developed what we call perennial allergic rhinitis. Similarly, we find cases of perennial asthma which started out as purely seasonal affairs but with each succeeding year the symptoms of the asthma persisted longer, until finally it was a perennial type of asthma.

The other sequelae of untreated asthma are too well known to receive any special comment other than the mention that these are emphysema, chronic bronchitis, deformity of the chest, and at times even bronchiectasis.

## CLINIC OF DR. FRANCIS L. FORAN

### ALLERGY CLINIC OF RUSH MEDICAL COLLEGE OF THE UNIVERSITY OF CHICAGO

#### THE ALLERGIC FACTOR IN MIGRAINE

It is not within the scope of this clinic to attempt even the most general discussion of the ancient riddle of migraine or of the modern riddle of allergy. But for the sake of clarity a brief definition of terms is desirable.

Migraine is a syndrome of severe headache, paroxysmal and recurrent, commonly unilateral, occurring usually in association with cortical symptoms (sensory, motor, or mental) and nausea or emesis. An enormous literature has produced a multitude of hypotheses. Outstanding is the striking influence of heredity. This fact together with the frequent occurrence of frank allergies in the individual or his family led Vaughan and numerous other authors, mostly in the past decade, to elicit evidence of allergy as a factor in migraine.

Allergy commonly connotes a demonstrable hypersensitiveness with an immunologic mechanism. However in its original coinage and wider sense the term simply implies an altered reactivity, an exceptional and inimical response of the organism to contact with substances in themselves usually innocuous or salubrious. In this extension the concept has the virtue of taking cognizance of certain striking clinical sequences, presumably of cause and effect and not otherwise classified, but the defect of supplying no *modus operandi* for their occurrence. There is impressive evidence that in this wider sense at least many cases of migraine are definitely allergic, with the reservation, however, that allergy is not usually the sole factor in their genesis.

**Case I.**—Migraine in a patient without other major allergy.

A. B., female, age twenty-six, single, clerk in a social service organization.

*Family History.*—There is no known case of epilepsy or insanity in any branch of relationship. The paternal grandmother died of "asthma." The father, deceased, was said to have had frequent headaches. The mother, still living, after her menopause developed periodic headaches which usually appear on awakening and are relieved by vomiting.

One brother had infantile eczema but no headache. Two sisters have neither headache nor allergy of any type. One cousin has eczema but no headache.

*Duration and Course.*—As a child the patient recalls widely separated attacks of sudden intense headaches with vomiting and visual disturbances.

Five years ago, at the age of twenty-one, the patient had a severe obscure illness ultimately diagnosed as tuberculous peritonitis. During convalescence the headaches became of frequent occurrence averaging once to several times a week.

*Character of Attack.*—The pain is located most intensely in the right occiput radiating thence over the entire head. It begins as a throbbing, developing into a heavy pressure or sense of expansion. The attack lasts usually a day but not infrequently continues for several days, the longest having been nine days in duration.

Nausea and emesis are not invariable accompaniments, but violent and persistent vomiting frequently occurs. The vomiting aggravates rather than relieves the headache. Hunger and abnormal appetite are often present during the attack. Violent sneezing, sometimes to the point of epistaxis, occasionally attends the headache. At other times the patient has morning sneezing without associated headache. This latter is the only symptom suggestive of other allergy in the patient.

*Aura and Cortical Symptoms.*—Usually before the pain begins the patient notices a blurring of vision and a sense of mental "heaviness" which seriously impairs her power of attention. These symptoms become very severe during the painful phase and continue on the day following.

*Precipitants of Attack.*—The menstrual period bears no constant relation to the headache. Neither mental nor physical fatigue seems to cause an attack. Prolonged use of her eyes does not occasion a headache despite the visual obscuration which attends the attack. Movement aggravates the headache once it has begun and a long ride on street cars seems to start a minor attack.

*Food Precipitants.*—The patient's own observation has established the striking relationship to specific food ingestion. Asparagus has repeatedly precipitated attacks. Chocolate, peanut, and tomato are also certain excitants. Two instances of her food sensitiveness were recently noted. On the occasion of testing the patient's leukopenic index to the ingestion of chocolate a large piece of chocolate was eaten at 9.15 A. M. At noon the patient felt "light-headed"; at 2.00 P. M. occipital headache had begun and at 3.00 P. M. she could not see clearly. At 3.00 A. M. the following morning she vomited without relief. The headache slowly abated the following day. Recently, while at a picnic, the patient had an attack which she attributed to the ride on a street car. On cross-examination, however, it developed that the patient had eaten a peanut butter and jelly sandwich. Despite her own observation on the rôle of peanuts in her migraine, she had overlooked the possible importance of the peanut butter.

*Skin Tests.*—Scratch tests with about 80 proteins including the implicated foods were entirely negative. Intradermal tests gave an indecisive borderline reaction to chocolate.

*Leukopenic Index.*—This was carried out with milk and chocolate taken on a fasting stomach as follows. White counts were made by the same technician using the same pipet, just before feeding the patient the tested food and at twenty-minute intervals thereafter. The results are shown in the tabulation.

*Comment on Case I.*—We have here a typical migraine of which the only known etiologic factor appears to be the ingestion of specific foods.

The skin testing was of little assistance in furnishing either new or confirmatory evidence. The leukopenic index gave a

## TABULATION

Time.	Leukocytes.	Polymorpho- nuclears.	Lympho- cytes.	Monocytes.	Eosino- philes.
-------	-------------	--------------------------	-------------------	------------	--------------------

Milk tested: 6/17/36. Nonallergic response.

9.15 A. M.	7250	53	39	3	5
9.20 A. M.	Milk—8 ounces ingested				
9.40 A. M.	6450	55	35	6	4
10.00 A. M.	7950	61	34	4	1
10.20 A. M.	6950	54	38	0	7

Chocolate tested: 6/20/36. Allergic response.

9.15 A. M.	7000	48	44	4	3
9.20 A. M.	Chocolate ingested.				
9.40 A. M.	6750	37	52	5	6
10.00 A. M.	6450	59	31	5	5
10.20 A. M.	5150	61	29	6	4

The leukopenic index was developed by Warren T. Vaughan after observation of the leukocytic response to the ingestion of food by allergic subjects. A non-allergenic food usually causes a postprandial leukocytosis; an allergenic food, a leukopenia. A variation of less than 1000 cells above or below the fasting level is regarded as an indeterminate finding.

fairly typical curve indicative of allergy to chocolate. Differential counts were added for their general interest. There have been some observations on eosinophilic variations but thus far the emphasis has been placed on the total leukocyte counts. A more extended use of the leukopenic index, especially in the skin-negative cases, promises improved results. Nevertheless the weight of the inquiry is borne mainly by the anamnesis and clinical trial.

Our service to the patient consists in putting proper emphasis on the food factor. Further supervision may elicit more information. Foods biologically related<sup>1</sup> to those known to be implicated will be held under suspicion. Thus susceptibility to peanuts will suggest the alternate trial and elimination of other legumes, such as peas, lentils, and beans; to asparagus, of the

<sup>1</sup>Ellis, Ralph V.: A Rational Grouping of Food Allergens. J. Allergy. 2: 246, 1931.

liliaceous vegetables, onion and garlic; to tomato, of the solanaceous vegetables, potato and peppers.

At present while the attacks have been reduced in frequency, many occur without a recognized occasion of food ingestion or indeed of any cause.

**Case II.**—Migraine in association with hay fever, pollen asthma, urticaria, and an anginoid syndrome to drug ingestion.

R. B., male, age thirty-two, single, an unemployed machinist's helper.

*Family History.*—The father and paternal grandmother had asthma. Both the father and mother had "sick headaches" with vomiting. Two sisters have attacks similar to his own and one has asthma also.

*Duration and Course.*—In childhood the patient had a few attacks a year and at the age of eighteen the frequency increased to about twice monthly.

*Other Allergies in the Patient.*—About ten years ago the patient developed a ragweed seasonal hay fever with severe asthma. These symptoms have been much curtailed by hypsensitization treatment in the past four years. Sharp skin reactions to pollen have been repeatedly obtained. It is deserving of particular comment that the headaches are not aggravated in the pollination season.

An attack of giant hives and severe asthma followed the ingestion of brazil nuts about six months ago. Again it is to be noted, that only a slight headache attended this attack.

The ingestion of aspirin, formerly taken for the headache, uniformly was the occasion for a precordial pain radiating down the left arm to the wrist. Ephedrine, used recently, not only moderates the headaches but, by the patient's volunteered statement, "has a quieting effect on the heart."

*Character of the Migraine.*—A recent typical attack was described thus: about four hours after eating some sausage meats, he had "gas" and "felt nervous." Shortly after headache began over the right eye gradually spreading down to the right ear. In a few hours vomiting of fluid material with no

food residue and without relief of the headache occurred. After about six hours the attack abated.

*Food Precipitants.*—All meats of the ungulate order but especially pork occasion headache. Chicken also to a somewhat less degree. Cured meats are tolerated better than fresh, and ham is sometimes eaten without sequel. Chocolate and beans are other known offenders.

*Other Precipitants.*—The patient has attacks very definitely occasioned by causes other than foods. Any nervous excitement, even such as a prolonged conversation, is likely to be followed by headache. Exposure to heat, sun or bright light are other occasions.

*Skin Tests.*—Scratch tests were entirely negative to all foods. Intradermal tests gave borderline positive reactions to chocolate and pork.

*Comment on Case II.*—Noteworthy in this case are the diverse manifestations of hypersensitiveness and the diverse nature of their occasions. The substances causing headaches do not cause asthma or urticaria and the reverse statements also hold. A pollen inhalant causes asthma and hay fever; a drug ingestant, angina; a food ingestant, urticaria and asthma; and still different food ingestants, migraine.

A diversity of mechanisms is also presumptive. Despite the evidence of the patient's atopic reactivity as seen in the positive skin tests to pollen, the foods definitely causative of the migraine give negative or indeterminate tests.

The therapeutic response to ephedrine is of interest. Despite the known sympatheticomimetic action of the drug, it has apparently a sedative effect on the "nervousness" incident to this migraine.

The case furnishes a good instance of group sensitization, in that the meats of the ungulates, beef, lamb and pork, all cause headache. A relative tolerance to the implicated meats after they have been cured is of practical significance. Food processing in either commercial or domestic preparation may be of advantage in the therapeutic management of allergies. The "hypo-allergic" milk of commerce makes use of this fact

and condensed, powdered, or malted milk may serve the same purpose. Heat by boiling, cooking, baking, or toasting in the home may modify the specific reactivity of a food protein.

It should again be noted that the food idiosyncrasy is simply one of several known excitants of the migrainous attack.

**Case III.**—Migraine in association with gastro-intestinal allergy.

A. J., male, age twenty-six, married, a medical student.

*Family History.*—His father and mother have no evidences of allergy. One brother who has urticaria, a chronic sinusitis and frontal headaches, gives positive skin tests to banana and tomato. One sister is very sensitive to strawberries and house dust, has dermatographia and urticaria but no headache. A second and third sister have migrainous headaches from milk, fish, and meat and are said to have given positive skin tests to these substances.

*Patient's Allergy.*—Several hours after the ingestion of milk the patient develops a unilateral headache. Some hours later a severe diarrhea follows.

A quantitative factor is present. A single glass of milk may be taken usually without symptoms. In this case, however, condensed or boiled milk will produce the same effect as the raw milk.

*Skin Tests.*—The scratch tests were entirely negative. Milk gave a negative intradermal test also.

*Comment on Case III.*—The negative skin tests in this patient are in contrast to the reported positive reactions of his brother and sisters. Whether this apparent variation is due to differences in technic, interpretation, or basic mechanism cannot now be said.

The quantitative factor may often be of importance in balancing a dietary with essential food elements. By not exceeding the level of tolerance, complete elimination may be avoided. The relation of quantity to the periodicity of symptoms was brought to attention in another instance. A school principal had been having migraine recurrently on Sunday

morning, which paradoxically he related to his week-end relaxation. After elimination diets had established wheat as a causative factor the periodicity was explained. The patient was in the habit of having a midnight supper largely of sandwiches on Saturday night; during the week, however, he ate very sparingly of bread and other flour products.

**Discussion.**—These cases are illustrative of the striking association of allergy and migraine in the individual or his heredity or both. The familial incidence has been estimated at 51 per cent (DeGowin), and where migraine is counted as an allergic characteristic, the family history shows upward of 80 per cent allergy (Sheldon and Randolph). The incidence of collateral allergy in the migrainous individual has been estimated at from 45 per cent (Westcott) to 80 or 90 per cent (Vaughan).

The repeated demonstrations from many sources of the sequential relationship of migraine to specific food ingestion would seem too definite to be mere coincidence. The presence of such an allergic factor in migraine has been set at from 35 per cent (Westcott) to 70 per cent (Vaughan). We have been impressed in this clinic, however, that, even in the presence of definite food specificity, there are usually other exciting factors of the migraine syndrome.

Skin testing has not been a productive procedure in our hands; in contrast to its great diagnostic value in asthma, hay fever, and eczema, it has given meager information in migraine, comparable to its very limited value in urticaria. This is in accord with the experience of Rowe but many careful allergists of wide experience report otherwise. Vaughan found skin tests a reliable lead in 50 per cent of his cases. It may well be that migraine is caused in some instances by an atopic and in others by a nonatopic mechanism. On the basis, therefore, of general experience thorough skin testing should be routine.

The leukopenic index has much promise as a diagnostic aid. Careful history taking, the use of the food diary and trial diets are of prime importance in diagnosis and confirmation of food sensitiveness.

The preponderance of certain foods as migraine excitants is of interest. A compilation was made of the first dozen foods in the order of their importance reported by six different authors (Vaughan, Alvarez and Henshaw, Sheldon and Randolph, Westcott, DeGowin, and Eyerman). An analysis shows that onion appears in 5 lists; cabbage, chocolate and pea, in 4 lists; coffee, egg, milk and wheat, in 3 lists; apple, beef, cantaloupe, celery, cucumber, orange, peanut, potato and tomato, in 2 lists. The following foods appear only once: banana, beans, carrot, chicken, lettuce, nuts, oat, peach, pork, radish, sweet potato, tea, veal, watermelon.

**Conclusion.**—An impressive mass of clinical data supports the contention that migraine is often occasioned by specific food ingestion. In this sense at least an allergic factor is demonstrated. The mechanism of its action and the extent of its significance in the total problem of migraine are still matters of dispute. But the statement is conservatively warranted that allergy has brought to the solution of this neurological enigma a contribution of real value.

## CLINIC OF DR. JOSEPH BRENNEMANN

### THE CHILDREN'S MEMORIAL HOSPITAL

---

#### CELIAC DISEASE

It may seem a bit startling to find a young lady of eighteen in a pediatric clinic. There are, however, certain diseases in which a presentation of the end-result and all that has led up to it is as instructive as the demonstration of a like case would be in the earlier, active stage. This is perhaps especially true in that of the young lady before us whose history is an epitome of a disease that is rare; that was once, I think, more frequent: that presents during the active period a striking, easily recognizable, clinical picture concerning the actual etiology and pathogenesis of which we are still quite in the dark; that formerly had a high mortality and, at best, led to years of profound nutritional and emotional disturbances; that in spite of our lack of knowledge as to the underlying cause and nature of the disease can now be cured within a reasonable time with a fairly full assurance of success. This is all the more interesting because the treatment is wholly dietetic. To one familiar with the disease it is probably evident from what has been said that we are dealing with celiac disease. You will come across it in the literature under a variety of names, of which only Herter's infantilism, and the German, *die Coeliakie* and *Chronische Ehrnährungs-störung jenseits des Säuglings Alters* need here be added to the English "celiac disease," introduced by Gee who first described the disease in 1888. It is essentially a pediatric disease, always beginning in late infancy or earliest childhood and rarely extending in an active form to adolescence.

As I have implied, this girl, in her own case, unfolds practically the whole story of celiac disease, individually and his-

torically, from the time when we stood almost helpless before a case and dreaded to see one up to the present time when the outlook is favorable enough for us to welcome each new one.

Before entering upon that story let us briefly see the end-result—itself interesting because still somewhat in dispute. It is evident from “Herter’s infantilism” that retarded growth was considered a part of the picture. A marked retardation of growth is always evident during the active stage and when this is prolonged the stature remains permanently below normal. It remains to be seen what the result will be in those patients in whom convalescence can now be reached so much more quickly than in former times. This girl presented an extreme picture of the disease. The active period lasted from the second to the sixth or seventh year, and, because of home conditions, progress was variable for some years longer. One has the impression that she is still undersized and yet, as you see, she is nearly as tall as her mother. (Another patient whom I have been able to follow to adolescence under more favorable surroundings is practically of normal height.) She is fairly well proportioned with a distinct tendency to obesity, a frequent end-result, and has a rather prominent abdomen that is a remnant of a condition that is one of the most striking and characteristic features of the earlier active stage of the disease. Her mentality is apparently somewhat below normal. During the early part of her disease this was a marked feature, her psychic response varying directly and proportionally with her physical state. In general children with celiac disease are normal mentally. Some have even thought them to be above average in that respect. The only other evident result in this instance is extreme dental caries that involves practically all of her teeth, most of them decayed flush with the gums.

Our patient was born March 16, 1918, and entered the Children’s Memorial Hospital for the first time December 18, 1920, at the age of two years and nine months. Because of language difficulties and ignorance on the part of the parents her early history was only vaguely obtainable. As nearly as could be ascertained she had had a diarrhea with some vomiting

for a period of six months or more. The stools were loose and pale, from 2 to 5 or 6 a day. The food was said to "pass through undigested." During this time there was a steady and very great loss in weight, the child slept poorly and could no longer walk or even stand alone. Her weight on admission was 15 pounds, about what we would expect a normal five months' old baby to weigh.

The general appearance was that characteristic of an advanced stage of the disease. There was extreme emaciation on the one hand and an enormously widely distended abdomen on the other. The child was pale and apathetic, except over the abdomen the skin was loose and unfilled because of the flabby and atrophied musculature and, even more, because of the almost complete absence of subcutaneous fat. The emaciation was especially marked in the extremities and in the gluteal region. The wasting of the buttocks has been given diagnostic significance by Miller as the "gluteal sign." It is only natural, however, that with a generalized loss of fat its absence should be most noticeable where it is normally most in evidence. The face often remains fairly filled out in contrast to the rest of the body, but in this child it was involved to a like degree. The skin hung in folds and the eyes appeared unduly large. There was no normal play of expression. She was wistful, pathetic, not happy rather than acutely unhappy, with no evidence of pain except when disturbed. The latter was probably due to latent scurvy, or possibly neuritis, which may accompany the disease in varying degree for obvious reasons. An evident tetany, a frequent accompaniment, doubtless played a part. The extremities were flexed at the elbows and knees and there was marked carpopedal spasm of both hands and feet. The Chvostek facial sign of tetany was present.

The teeth showed widespread caries. The hemoglobin was reported as 75 per cent; the red blood cells as 4,000,000; the white blood cells as 10,200. The temperature was subnormal.

The abdominal distention was perhaps the most arresting feature of the whole picture. The abdomen seemed out of all proportion to the rest of the body, not especially tense, not

tender, but extending in all directions as if pushing other structures out of the way. In spite of the thin wall there was no evidence of an intestinal pattern—hence no increased peristalsis. The distention was evidently due to hypotonicity of the intestinal and abdominal walls and the presence of an abnormal amount of gas in the intestinal tract, both a cause and an effect. It was natural that the intern should record his impression that the child had a tuberculous peritonitis, a mistake that is probably made at some time in nearly every case. Tuberculin and Wassermann tests were negative.

The diagnosis of celiac disease ultimately rests on the nature of the stool, the color, odor, consistency and volume of which are pathognomonic in the proper clinical setting. The stool is always grayish-white in color and has usually a degree of foulness rarely attained by any other. Its advent is evident in the room and nurses are loathe to save the stools even in a closed container. They may be hard and formed and reduced to 1 or 2 a day during periods of more favorable progress; or frequent, soft and mushy during periods of exacerbation that are so prone to occur, often inexplicably. They rarely exceed 4 or 5 a day. They have a greasy appearance at all times, notably so when loose. They then resemble oatmeal porridge as long ago pointed out by Gee whose classical description has left little to be added. More striking than anything else is the amount of stool passed in the twenty-four hours. This often exceeded more than a pound a day in our patient. Freise and Jahr reported eight to ten times as much stool in 2 children with celiac disease as in two normal controls on the same intake of food. All of these characteristics are evidently due to non-absorption of fat.

During the first seven months in the hospital the condition remained practically unchanged. All sorts of things were tried, both empirical and seemingly rational in our then current state of knowledge, without tangible progress. Finally, each new resident took a fling at it in the light of what he had been taught in school or in some other medical center. Characteristically, things got alternately better and worse. Tetany

was present at times and again absent. The disposition varied with the nature and frequency of the stools, a pretty accurate barometer of progress. Her weight varied from 15 to 16 pounds and when it once got up to 17 pounds and her stools were formed and reduced to 1 a day, she was allowed to go home.

Five weeks later (8/24/21) she was readmitted. During the stay at home there had occurred one of those catastrophic losses in weight and general well-being that are so frequent in these patients following errors in diet, often enough without evident reason. She had lost 4 pounds and now weighed 13 pounds, pretty nearly an all time low for a child of three and one-half years.

In June, 1921, Dr. John Howland delivered his presidential address before the American Pediatric Society on the subject of Prolonged Intolerance to Carbohydrates. Unfortunately, but characteristic of the man, this paper was allowed to remain buried in the Transactions of that Society from which it has only been exhumed from time to time by those especially interested in the literature of celiac disease. Contrary to the prevailing view that celiac disease was due to an inability to digest and utilize fat, Howland pointed out, based on a study of more than 30 cases, that the essential trouble was a chronic intolerance for carbohydrates. As a natural corollary he advocated a dietetic régime of 3 stages, each varying in length according to the severity of the disease and the reaction of the child:

1. "Protein milk alone until the stools are firm, the distention very slight, the gas not in excess and the appetite good."
2. Protein milk with the addition of "curd, scraped beef, certain forms of cheese, egg white and eventually the whole of egg" and "some orange or tomato juice."
3. The cautious addition of vegetables well puréed, first the 5 and then the 10 per cent types, followed as tolerated, finally, by bread, cereals and potato.

Profoundly impressed by this paper we put our patient on a high protein daily diet of a quart of protein milk, scraped beef, eggs (soon discontinued), diaprotein muffins and small amounts of vegetables, fruit and bread. It will be noted that,

through a misinterpretation, this diet did not conform to the fundamental ideas advanced by Howland in that a small amount of vegetables, fruit and bread were permitted. Too, we erroneously thought that our patient was old enough not to require a rigid adherence to so limited a diet. She was kept on this diet with occasional variations for about a year. In the first month she was greatly improved and gained  $4\frac{3}{4}$  pounds, up to  $17\frac{3}{4}$  pounds. The next month she lost  $2\frac{1}{2}$  pounds. Her weight fluctuated widely for the rest of the year. Toward the end of the year she was put on a general diet, advocated at the time by certain German clinicians. The stools rapidly became loose and more frequent, there was a sharp drop in weight and at the end of that period she weighed only 16 pounds at four years and seven months of age.

She was now put on a rigid high protein diet—or, I would prefer to say, *on a minimal carbohydrate diet*. This consisted of protein milk (with occasional change to buttermilk), scraped beef, diaprotein muffins, gelatin and cottage cheese, of each as much as she cared to eat. The clinical note soon reported: "She relishes this diet and the stools begin to improve." Her disposition changed; she became happy, and talked and played with other children. On this rigid diet for seven months her stools remained at 1 or 2 a day, were formed but still large and rather offensive, and her monthly gains in weight were 2, 2, 2, 2, 2, 2, and 3 pounds. In seven months she had nearly doubled her weight, going from 16 to 31 pounds.

One cereal a day was now added to her diet. There was a prompt return of loose, more frequent, greasy stools and a drop, or rather a downward push, of 2 pounds in weight which she only regained after another two months. Progress notes at this time reported her to be: "rather pale, not so active, losing weight; stools much softer and of lighter color. Patient has been acting drowsy, toxic. Chvostek sign positive." On returning to the previous rigid diet plus 3 bananas daily, she gained rapidly as shown by monthly gains of 3, 2 and 1 pounds. In spite of the serious setback she had gained 19 pounds during the year, going up from 16 to 35 pounds. Two years later she

was discharged at the age of seven years, eight months, weighing 48 pounds. Her last record, four years later, showed her weight to be 63½ pounds and her height five feet, one inch. She was then eleven and one-half years old. During the latter part of her stay in the hospital she was gradually switched to a general diet which was continued at home. Only minor upsets occurred during this time. Her condition since that time has been much as you see it now.

What do we know about the nature of this strange disease? Necropsies have thrown practically no light on the subject. Some of the reports have been wholly negative, others contradictory, and one rather gets the impression that such findings as atrophy of certain viscera, of the intestinal mucosa, etc., are an effect, not a cause. From the gross appearance of the stools and from microscopic and chemical analyses it was evident that these were largely made up of fat derivatives. It was natural to assume that we were dealing with a chronic fat intolerance. It was natural, again, to assume that there was basically a pancreatic deficiency. This seemed improbable, however, inasmuch as the disease was always preceded by a normal condition and, under favorable conditions, a full normal state recurred. It was even more negatived by the fact that while in a pancreatic deficiency the fat is not split, it is in celiac disease. In the latter neutral fats, fatty acids and soaps are all found in such amounts that they determine both the characteristic consistency and the abnormal volume of the stools. So great is this volume that it has even been held that there was an endogenous transfer of fat from the body into the intestinal canal, but this lacks support. Whatever the pathogenesis of the disease may be, the fact stands out that the fat is not absorbed normally. Why, no one knows.

Attempts have been made to solve the problem by a study of the intestinal bacterial flora, notably by Herter who published his results under the title of Intestinal Infantilism in 1909. Based on the fact that he found a predominantly gram-positive flora made up of *Bacillus bifidus*, *Bacillus infantilis* and gram-positive cocci which normally characterize the intes-

tinal flora of the breast-fed infant stool, he postulated the persistence of this condition into the artificially fed period as the cause of celiac disease. This view no longer has any adherents. The endocrines, the sympathetic nervous systems, an abnormal constitution, a neuropathic state, dysentery, acholia and avitaminosis, have naturally all been drawn into the picture as interesting but futile speculations.

The observations of Howland, that led to the view that there was essentially a chronic carbohydrate intolerance, have appealed to me as basic and my own experience and a perusal of the literature has not changed that view except in minor respects. I have not adhered to a graduated 3 phase diet but have put even infants (the disease rarely begins before the second or third year) on as nearly a carbohydrate-free diet as can feasibly be devised and can only say that for the first time in my experience this furnishes a régime that has uniformly led, sometimes to wavering, but always to satisfactory results and to a fairly early cure. That fresh whole milk is not tolerated has long been known. That the fat is not the basic noxious agent would seem evidenced by the fact that protein milk is well tolerated in spite of the fact that it has a fat content comparable to that of whole milk. That there is no danger of carbohydrate starvation on a high protein diet was emphasized by Howland in that an adequate amount of carbohydrate is derived from the protein. Evidence has been presented by Nelson that dextrose is tolerated in large amounts, in direct opposition to a statement by Howland that it is not. I have had no experience on which to base an opinion but am inclined to accept Nelson's conclusions. There is practically no dissent from the view that starch is the one dangerous food element and that starchy foods must only be introduced after convalescence has long been established and even then with great caution.

My own procedure in recent years has been as follows: As the liquid food I give protein milk as much as the child will take at the usual intervals. Buttermilk may be given equally well for a time. No carbohydrate is added; if sweetening is

needed a grain of saccharine is added to a quart of either food. Slightly broiled scraped beef is offered three or four times a day at the usual feeding times. To this are added, *ad lib.*, cottage cheese, gelatin, egg white and muffins made of diaprotein or other low-carbohydrate flours, 2 or 3 ounces of orange juice and a teaspoonful of cod liver oil, or an equivalent amount of viosterol or percomorph oil. If tolerated 1 to 3, or more, bananas are added. These must be fully ripe, mealy, with black or black-dotted rinds. There is usually an almost immediate improvement in the nature of the stools, the gain in weight and the child's disposition. After a variable time, usually a matter of months, puréed vegetables and fruits are added with due caution. Still later toast, and lastly starchy foods such as cereals, usher in a general diet, including boiled, or evaporated milk. Vigilance must still be maintained. The general dietetic dictum, "advance slowly, retreat precipitously," is nowhere more applicable than here. Drugs play no part, except the occasional indication for iron. Transfusions may help, but are rarely necessary. Ultraviolet rays are valuable if cod liver oil is refused, or not well tolerated.

Other methods of treatment have been advocated. Haas has especially popularized the use of bananas as a sort of basic diet and has given as many as 16 a day to a child. Bananas are undoubtedly well tolerated in many, probably most, cases and are therefore a valuable addition. This has been confirmed from many sources. Celiac disease is, however, a very notional disease, has possibly not a unitarian etiology, and the banana is not a specific. As in the use of all other foods caution must be observed and theory and authority may have to give way to experience in the individual instance.

Celiac disease is a rare disease and I have had no occasion to try out the more rigid fruit and vegetable cure of Franconi. This consists in giving first the juices of oranges, lemons, berries, grapes, etc.; later, bananas, scraped apple, pears, etc.; and still later, puréed vegetables, all in gradually increasing amounts. Cane sugar and starchy foods are considered harmful even in small amounts. Good results are reported on this régime.

Many Continental observers have advocated a liberal general diet, with few interdictions. I rather think these views hark back to a time when we knew less than we do now about the treatment of celiac disease and were satisfied with less assured results.

As a curiosity, it would seem to me, may be mentioned finally the *Übungs Diät* (exercise, or stimulation, diet) of Schick and Wagner. This consists in giving just the articles of diet that are not, or poorly, tolerated with the idea of stepping up the tolerance by exercise, or stimulation, of the digestive glands involved. A reported mortality of 40 per cent in 5 cases hardly furnishes an incentive to try this unique procedure!

In the treatment of diseases that are rare and, in the past, have been discouraging—not to say baffling—we are prone to follow a course that we have found leads to results. For that reason I still use a high protein diet, or rather a low carbohydrate diet—or still more specifically, as a desideratum, a starch-free diet.

## CLINIC OF DR. FRED M. DRENNAN

### MERCY HOSPITAL

---

#### AMEBIC DYSENTERY

I AM going to start this clinic with a brief history of the case being demonstrated as it is fairly typical.

A young man, twenty-eight years old, came to my office a few months ago complaining of diarrhea. His work has been that of a salesman in the southern part of the United States. While in North Carolina, six months previously, he had been "upset by food" taken and had a severe though short duration diarrhea with abdominal cramps, tenderness, nausea and vomiting, mucus but no blood seen in the bowel movements. He did not know about temperature but felt he probably had no fever. He felt weak and "played out" but went on about his work and in a few days was seemingly all right. Following this, he had recurring short duration diarrheal attacks becoming more frequent, so that during the two months before examination he had continual loose movements, three to six daily, watery in consistency, with associated rumbling and gurgling, cramp-like pain at times severe during defecation, marked generalized abdominal tenderness, mucus and blood in the bowel movements. There was only a slight loss in weight, though he felt tired and worn out. He complained of nausea and lack of appetite, but had no vomiting after the first attack.

At our examination the blood pressure was 114/86, temperature 98° F. Urine was negative as to albumin, sugar and casts. Hemoglobin was 80 per cent. Ewald meal showed free acid 45, total 81; benzidine test for blood negative. Bowel movements were mushy to watery, and on examination showed benzidine ++++. Physical examination was essentially

negative except for a markedly spastic, ropelike, and tender colon. Rectal examination caused no particular pain, and no masses were felt. A second stool examination showed mucus and blood; on warming specimen for microscopical examination amebic organisms were demonstrated.

A clinic on "amebic dysentery" is always an interesting subject for the teacher because it must deal with a condition concerning which medical investigation has had a great deal of uncertainty. In this clinic I am going to mention only things that seem at the present time to be fairly stable.

By the term "amebic dysentery" we mean a disease caused specifically by the *Endamoeba histolytica*, the lesions originating and being chiefly in the large intestine though liver complications are present; clinically characterized by diarrhea with blood, pus and mucus in the bowel movements. There is a tendency for the symptoms to be intermittent which perhaps increases the difficulty in diagnosis, the locating of carriers, and the development of complications. Many cases are seriously disabling if allowed to develop, so that any diarrhea should be investigated thoroughly even though we may feel it is a relatively simple condition. The first intimation of amebae being associated with dysentery was made by Lösch in 1875, but because similar organisms were found in healthy individuals and in other conditions associated with diarrhea, it was not taken seriously. Later investigators noted the association regularly and also found the organisms at postmortem in the ulcerative lesions in the mucous membrane of the gut. Then Schaudinn suggested the presence of 2 distinct organisms of similar morphology, both parasitic, but one (*Endamoeba coli*) nonpathogenic, the other (*Endamoeba histolytica*) pathogenic and the cause of the condition known as amebic dysentery. For the purpose of this clinic and of practical medicine we may only mention in passing the other endameba found in bowel movements and the types that grow freely in bowel movements, ice cream and simple media, which are not a cause of serious pathology.

It is readily seen then that a diagnosis of endamebic dys-

entery must rest, as in our case, on two important factors, first the clinical story which may be that of acute attacks of diarrhea or mild attacks which are not severe enough to keep the patient from his work but which recur or persist for a few weeks and then clear up without definite treatment. Regularly, the colon is spastic and tender to pressure; cramplike pain may be severe with relief by passing gas and by bowel movements; temperature moderately raised, appetite lessened and nausea present, as might be seen in a simple diarrhea. During the intermittent stage the patient may feel normal. In severe or complicated cases symptoms are varied by the complications present as liver abscess, etc.; on examination of the bowel movement usually one finds fecal material mixed with mucus, pus and blood (not the watery secretion found in bacillary dysentery). In this mucous and bloody material the active organisms are found. Fresh warm specimens give best results, though specimens which are kept cold and warmed just before examination are very satisfactory as the organisms become active on warming. It is to be noted that in specimens kept at body temperature the organisms deteriorate rapidly so that they are not visible. Specimens for examination for the trophozoites may be mounted in saline solution or a dilute aqueous solution of eosin so that the organism will appear white on a pink background. The movement is sluglike, likely to be fairly active, red cells are ingested and the nucleus almost invisible unless stained in some way. If direct examination does not show organisms, saline cathartics may be given or material may be secured directly from the ulcers by rectal tube or proctoscopic examination. Single examinations with negative findings do not rule out a positive diagnosis. The finding of other organisms in material from the ulcers is to be expected because in the gut wall there is regularly a secondary infection. This may be responsible for difficulty in diagnosis in some cases in which an ulcerative colitis (idiopathic) is diagnosed, yet the case improves on emetin or similar treatment. In looking for carriers one must find encysted forms, usually by staining methods. Culture methods are technically difficult as are the

complement fixation methods. Though both may be of value if done by experts, neither is practical for a physician.

The life cycle of the *Endamoeba histolytica* is simple, consisting of two stages, first the trophozoites or motile forms which multiply rapidly in the large intestine producing the lesions and the symptoms of the disease. These motile forms are passed in large numbers but they die quickly when exposed to the air or stomach content and so do not transmit the disease. In the gut, conditions that are not compatible with growth of the trophozoites develop and they reproduce less rapidly and finally become encysted and are passed out of the bowel. These cysts when swallowed are broken up in the small intestine and a four-nucleated ameba is freed. These are held at points of stasis in the gut, divide into typical trophozoites and the usual lesions of amebic dysentery result. This makes the source of infection a carrier, who though passing cysts may be free from symptoms, perhaps may never have had enough diarrhea to fix it in his memory as being important, yet be the cause of epidemics as a handler of food, etc. The practical point is that any patient who has had amebic dysentery should be checked at regular intervals for months to be sure he is not a carrier.

The pathology of the disease is primarily that of the intestinal ulcers, commencing in the cecal region though the entire large gut may be involved; the lesions start as a small inflammatory area, surrounded by a hemorrhagic area. In the center necrosis of the epithelium takes place, into this the amebae pass destroying tissue, undermining the submucosa, giving an oval undermined erosion. Usually enough inflammatory reaction takes place so that perforation does not happen; between the ulcers are areas of fairly normal mucous membrane. As healing takes place, marked scar tissue develops which produces obstruction and, if the gut is pliable, dilatation above the point of obstruction. The organisms are found in the submucosa, in muscle layers and in small venules, in which they may be carried to the liver giving the complication of liver abscess. These abscesses are usually single, may be in any portion of the liver; occasionally there may be multiple abscesses or

numerous miliary lesions. Usually there is a destructive necrosis of liver tissue without liquefaction or marked inflammatory reaction in surrounding tissue. The lesion is walled off by granulation tissue and if secondary infection takes place, as it usually does, one gets the reactions due to the invading organisms, plus the findings of the amebae. These abscesses may be fairly quiescent for weeks, may gradually increase in size, may rupture into surrounding tissue, lung, pleura, peritoneum, or externally. If walled off and drained, they may heal readily. While liver abscess is noted as a part of the pathology and may be thought of as a complication, it must be remembered that intestinal ulcers followed by liver abscess normally indicate amebic infection. Liver abscess may be present without demonstrable lesions in the gut. Other pathology as complications include peritonitis from perforation or near perforation, appendiceal involvement, very infrequently urinary tract infection by transplanting or perforation, partial or complete intestinal obstruction. In all locations the ulcers are prone to become secondarily infected, giving a changed symptomatology and pathology and frequently increasing the danger to the patient. Certain authors go so far as to state that all ulcerative colitis is likely to have been primarily amebic, later being complicated by the secondary invading organisms. This gives the basis for anti-amebic treatment in all such cases with improvement resulting in a considerable number.

We began our history with the statement that our patient worked in the South and it is a fact that amebic dysentery is more common in tropical countries, not as an epidemic, but generally present. It is endemic in temperate zones, as our Chicago infection of a few years ago. Probably it is fair to say that we have cases quite regularly with us, that could be diagnosed if more frequent and careful microscopical examination of the bowel movements were made. Carriers, especially those who may handle food, vegetables that have been grown on ground fertilized by human excreta, contaminated water or milk supply, etc., must all be considered in the insidious extension of the disease. Careless laboratory technic is a possible

though probably not a frequent cause of infection. It is very difficult to establish an incubation period, inoculation experiments placing it at from thirty to one hundred days with the probability being that only a small percentage of people ingesting cysts actually develop amebic dysentery. Intestinal stasis and constipation on a basis of obstruction seem to increase the probability of pathology.

I am going to list definite cases in discussing the differential diagnosis, because in each the diagnosis of an amebic dysentery was considered during the course of the disease.

First, a twenty-five-year-old school teacher gave a history of acute and persisting diarrhea for several months, mucus and blood in the bowel movements, marked loss in weight, severe generalized abdominal cramps, and tenderness over the entire colon particularly in the right lower quadrant. At the time of examination her temperature was  $102^{\circ}$  to  $103^{\circ}$  F. in the afternoon. On fluoroscopic examination with a barium enema there was a definite filling defect in the cecum; the rest of the gut was spastic but not obstructed. No amebae were found on stool examination, nor were tubercle bacilli, though operation confirmed the probable diagnosis of tuberculosis.

The second patient was seen at the age of fifty years, with a history of cramplike pain in the lower abdomen, generalized but worse on the left side, frequent desire for bowel movements, 4 to 6 movements daily, with the passage of soft material frequently containing mucus and blood, and spastic and tender colon. The patient sat on the toilet to empty bladder because of the passage of bowel movement on straining. Appetite was diminished. He had slight nausea, but no vomiting, and had lost 10 pounds in weight. On examination temperature was  $98.6^{\circ}$  F., blood pressure 128/70, hemoglobin 90 per cent, and urine negative for sugar and albumin. Stomach secretions were normal and no blood was found. Bowel movements were mushy, with small amount of pus and persistent blood, but no amebae. Rectal examination revealed a small firm nodule, like a polyp, about 4 inches from the rectum. Fluoroscopic examination with barium enema showed partial obstruction in pelvic loop

of gut. The barium, however, passed in sufficient amount to fill the gut, showing no further filling defects. There was a definite delay in expelling the enema which caused the patient considerable distress. Proctoscopic examination revealed the polyp felt by rectal examination but could not reach the region of partial obstruction. A diagnosis of malignancy was made and operation advised. At surgery, resection revealed numerous flat polypi with broad bases; 2 large ones separated by a distance of 3 inches had undergone malignant degeneration, giving the findings of blood in the bowel movements. The mucous membrane between these lesions was normal. The patient has remained well following resection.

Third, a man, fifty-five years old, came in complaining of abdominal cramps for a period of three months, coming in attacks, associated with desire and straining at bowel movements. The material passed was mushy to watery in consistency. There was some rumbling, with relief of cramp by water enema; he sometimes used 2 to 4 enemas during twenty-four hours. Mucus was seen in the bowel movements and frequently there was a rather profuse amount of bright red blood. He had lost 10 pounds in weight but was working regularly.

On examination he weighed 144 $\frac{3}{4}$  pounds; temperature was 98.4° F. and blood pressure 150/104. Urine was negative for albumin and sugar. Hemoglobin 80 per cent. Ewald meal showed free acid 18, total 30, and negative benzidine test. Rectal examination was negative. The left side of the abdomen and the descending colon were tender to pressure. The first bowel movement examined was mushy in consistency, but negative to blood. A second series of bowel movements showed clots of blood, not digested, but no amebae. During hospital examination bowel movements at one time might be free from blood, but within an hour the patient would have a desire for movement and pass a large amount of fresh red blood, very definitely different from the usual occurrence in carcinoma, bleeding polyp, tuberculosis, or ulcerative colitis. Fluoroscopic examination with barium enema revealed a definite obstruction in the lower portion of the descending colon tight

enough so that only a small stream of barium would pass through. The enema caused a great deal of pain.

A diagnosis of malignancy was made, mention being made of the fact that certain of the bowel movements were free of blood which is not usual in a cancer of the colon, particularly the *descending portion*. At operation a palpable mass was felt at the location described; it was not hard, but the lumen of the gut was almost obstructed so resection was done. The mass was about 1 inch in diameter and cauliflower-like in appearance; on microscopic examination it was found to be a rare nodular hemangioma. The patient made an uneventful recovery following resection.

Other conditions which may give the same picture as the cases cited are infected diverticulitis, infected ulcerative polyp (nonmalignant), etc. Idiopathic ulcerative colitis furnishes the most difficult differentiation. The symptoms are more persistent and have all the earmarks of severe amebic dysentery. Except for the causative organisms, the clinical and laboratory findings are similar. One cannot be criticized too much for using anti-amebic medication in cases where the organism may not have been found, yet clinical or proctoscopic examination may be suggestive of amebic infection. Bacillary dysentery, food irritation, toxemias as from the thyroid or uremia, etc., also may be mentioned in connection with the differential diagnosis.

The treatment of amebic dysentery should take into consideration the entire clinical picture and should include the nourishment and general condition of the patient as well as the elimination of the causative organism. This means rest in bed, sufficient bland waste material, free food to provide nourishment, preparations of opium like deodorized tincture, 10 to 15 drops five times daily, paregoric, etc., to control the diarrhea. Bismuth preparations also help to control the diarrhea. As to specific treatment we have the arsenic preparations, such as stovarsol, in 3- or 4-grain doses three times a day for four to seven days, with a rest period of seven days and then resumption of treatment, treparsol, 5 grains, three times a day for

seven days with a seven-day rest period, yatren, 4 grains three times a day for seven to eight days, carbarsone, 4 grains twice daily for seven to ten days, and emetin which is given by intramuscular injection,  $\frac{1}{2}$  to 1 grain daily, for five to seven days, with a corresponding period without medication. With all arsenic preparations one must watch for symptoms of arsenic poisoning, and when noted promptly stop the drug, whatever it may be, until certain that the accumulative effect has had time to wear off. With emetin the toxic effect on the heart muscle is probably the greatest danger, making it a drug which requires greater attention even than the arsenic preparations.

I have been partial to stovarsol, as I used it early and find that if one watches for arsenic poisoning, it gives very satisfactory results. One must be cognizant of the fact that patients react differently; one patient may be influenced very little clinically or in the laboratory findings in the bowel movement by one drug, yet will get rapid clinical improvement and freedom from organisms from another type of medication. Each patient must be considered as an individual entity and clinical improvement, clearing of bowel movements from cysts and active organisms, and healing of ulcers must all result if treatment is satisfactory. Liver abscesses and other complications must be treated surgically as the condition demands, in addition to the regular medication outlined.

In the final analysis, one must remember and impress upon the patient that recurrences are frequent, to be expected, and dangerous, when present, to him as well as to his associates. This means repeated examinations and, if necessary, repeated and varied treatments with no immunity established from previous attacks.

## CLINIC OF DR. RALPH C. BROWN

### PRESBYTERIAN HOSPITAL

---

#### DIAGNOSIS AND TREATMENT OF DUODENAL STASIS

DUODENAL stasis may arise from a wide range of pathological processes causing obstruction of the duodenum in any of its four anatomical portions. Thus, duodenal ulcer, carcinoma of the papilla of Vater, compression of the duodenum by a diseased gallbladder, adhesive bands constricting the duodenum, and carcinoma of the head of the pancreas, may be noted as not infrequent causes. I shall confine the discussion at this time, however, to the type of chronic duodenal stasis caused by arteriomesenteric compression of the third portion of the duodenum.

The interesting problems involved in the general subject of chronic duodenal stasis cannot be approached with clearness of understanding without brief reference to that relatively recent period in our morphological evolution in which the progenitors of men were four-footed animals, for in the four-footed animals the entire duodenum is a free intraperitoneal loop, with a mesentery hanging freely down in a vertical plane. When our forbears reared up on their hind legs and began to walk like man, there took place a marked change in the anatomical relationships of the bowel, and especially of the duodenum. The mesoduodenum disappeared, the duodenum posteriorly was deprived of much of its peritoneum, and as a result of the upright posture and rotation of the large bowel around the root of the mesentery, we find in man the *third* portion of the duodenum lodged in the acute angle between the spine and the root of the mesentery.

During the last decade of the last century, Dr. Lewis

Dwight, Professor of Anatomy at Harvard University, carried on an intensive study of variations in the anatomical relationships of the third portion of the duodenum, making wax casts in situ in 54 cadavers. These casts of the bowel showed varying degrees of compression of the duodenum in its third portion, as evidenced by indentations produced posteriorly by the spine and anteriorly by the root of the mesentery and the mesenteric artery. Thus it may be readily understood that the duodenum, placed as to its third portion in so precarious a position, may be compressed to a degree giving rise to obstructive symptoms as a result of any factor causing an increased drag on the root of the mesentery, especially when associated with lordosis of the spine.

Obstruction of the duodenum by this mechanism was recognized by Rokitansky in 1848. Excellent reviews of the literature with a series of case histories have been published by Kellogg, Higgins, and others. In the 1933 volume of the Transactions of the American Surgical Association may be found a thoroughly sound exposition of the subject by Eugene Pool, Walter Niles, and Kirby Martin. However, careful reading of the case histories recorded by these various writers shows a rather wide and variable range of symptoms resulting from duodenal stasis caused by arteriomesenteric obstruction. The diagnosis can be established with certainty only on the basis of careful roentgenologic observations, and later I shall emphasize the fact that minor degrees of lagging of barium in the second and third portions of the duodenum are all too frequently interpreted as the basis for variable local and general subjective symptoms which a more conservative viewpoint might consider due to causes other than chronic duodenal stasis. In none of these protocols was I able to find a symptom picture showing so clearly the widely intermittent, acute paroxysmal type of attacks suffered by the first 2 cases I shall describe.

The first case is that of a physician, age forty-three. For no less than twenty years he had had attacks of agonizing abdominal pain associated with the most intense nausea and

vomiting, each attack lasting from three to five days, the attacks occurring on an average of three to five times yearly. Between attacks he enjoyed a normal digestive function with freedom from abdominal distress. The onset of attacks occurred suddenly without warning symptoms, frequently awaking him from sound sleep. The initial symptoms were nausea and vomiting, immediately followed by severe, rhythmically recurring paroxysms of "tearing" pain, centered just to the right of the umbilicus and radiating to the lumbar region bilaterally. The pain was severe enough to produce profuse perspiration and render him oblivious to his surroundings. After protracted retching and vomiting some temporary relief from pain might be had, but within a brief time there would be recurrence of intense nausea, vomiting, and rhythmic type of pain. The vomitus at onset was fluid in character, containing mucus and bile. Upon two occasions the vomitus contained food eaten twenty-four hours previously. During attacks everything ingested would be immediately vomited, hence as the attacks progressed through three to five days continuously day and night, a marked degree of dehydration and profound prostration occurred with great loss of weight. The attacks ended abruptly and within a few hours normal ingestion of food and fluid could be resumed. It should be noted that the patient had no headache, which Dr. Crile considers a symptom of so much importance in his group of chronic duodenal stasis cases. Over a period of twenty years this physician had had scores of attacks of the character described, and the similarity between this clinical picture and that of the gastric crises of tabes dorsalis requires no comment. Physical examination, however, was negative with the exception of emaciation, and syphilis was excluded in so far as possible by serological tests and careful neurological examination.

Fluoroscopic examination in this case revealed normal filling of a moderately dilated stomach showing a marked degree of hyperperistalsis. Barium immediately passed on into the duodenum, the cap (showing no defect in contour) and the second portion of the duodenum filling to very large size, the

dilatation extending throughout the entire second portion. In spite of very vigorous peristalsis and an equally marked anti-peristalsis throughout the extent of this greatly dilated duodenum, a very long delay occurred before any barium passed on into the jejunum and long after barium had entirely left the stomach, a large pool of barium showing a fluid level remained in the dependent part of the second portion of the duodenum. Films show the size of this dilated duodenum to be approximately one third that of the moderately dilated stomach. A diagnosis of duodenojejunal angle obstruction was made and the abdomen was explored by a distinguished surgeon. Finding nothing in the region of the angulation other than the fact that the duodenum was fixed firmly to the abdominal wall by a very short ligament of Treitz, the abdomen was closed after removing the appendix. Two years later the patient returned with a continuation of the same distressing symptoms and as x-ray examination disclosed the same striking evidence of arteriomesenteric duodenal obstruction, a duodenojejunostomy was immediately performed with subsequent complete relief of symptoms during the period of years which has intervened. Fluoroscopic studies made after operation showed normal emptying time of the stomach and duodenum.

The second case is that of a young man of twenty-five, who had had paroxysmal attacks of epigastric pain associated with nausea and vomiting for ten years. The attacks would last two to three days, occurring about a year apart, but for the last three years the recurrent attacks had had a duration of about two weeks. The attacks would come on suddenly with severe pain and cramps in the epigastrium, rapidly spreading to the entire abdomen. The pain would double him up and during an attack he could not bear to have the abdomen touched. There would be profuse perspiration and a temperature rise to 102° F. and even to 104° F. He was often given hypodermics of morphine for relief, always losing a great deal of weight during the attacks and feeling weak for a long time after recovery. He had consulted many physicians and the diagnosis commonly made was that of gastritis or appendicitis. He was

of robust type, his normal weight being 180 pounds, was married and had two healthy children.

This patient entered the hospital on my service as an emergency case, having been suddenly seized with very severe epigastric pain a few hours before admission, associated with the most intense nausea and vomiting. Examination revealed some rigidity in the upper abdomen, no distention, temperature normal, urine normal, leukocytes 20,000. He was doubled up with pain and required morphine. A tumefaction in the right rectus region was seen with visible duodenal peristalsis from right to left. The second day temperature rose to 100° F. and the third day to 102° F. Pain, vomiting, fever, and high leukocytosis continued into the fourth day. Blood chlorides dropped to 300 mg. and the clinical picture was that of an acute surgical abdomen due to high intestinal obstruction.

**x-Ray Findings.**—Marked dilatation of second portion of the duodenum with delay in passage of barium into jejunum. A diagnosis of duodenojejunal angle obstruction was made, and twelve days after admission laparotomy showed great dilatation of the duodenum up to the root of the mesentery, but no other pathology with the exception of a slight, recent plastic exudate about the duodenojejunal fossa. An anastomosis between the dilated duodenum and the jejunum was made with uneventful recovery and complete relief from symptoms. Within six weeks the patient had regained the 25 pounds which had recently been lost. Here again we find a clinical picture of clearly intermittent, acute paroxysmal attacks, occurring very many times over a long period of years, causing the patient to be desperately ill for several days, with normal digestion between attacks. There can be no reason to doubt that in this, as in the preceding case, the obstructing factor was arteriomesenteric occlusion of the third portion of the duodenum. It is interesting to speculate on the mechanism involved. The second case had a history of troublesome constipation. It seems not unlikely that an overloaded colon may have intermittently caused just enough increased traction on the mesenteric root to precipitate the recurrent attacks of duo-

denal occlusion. It should again be noted that headache was not a part of the clinical picture.

The third case may throw light on the possible influence of two other factors in the causation of arteriomesenteric occlusion and immense dilatation of the duodenum, *i. e.*, emaciation and disturbance of the nerve supply to the duodenum causing atony. The patient was a man, thirty-nine years of age, seen in consultation at the Presbyterian Hospital. Four years earlier gallstones had been removed and the duodenum reported normal. Four months before my observation of the case a highly toxic goiter had been diagnosed and ligation of the vessels carried out with no improvement. Weight was rapidly lost and two weeks after ligation of the thyroid vessels he began having attacks of abdominal pain and vomiting, which became progressively more frequent and severe until his condition became desperate. His weight dropped from 125 to 91 pounds, he became delirious, dehydrated, profoundly toxic, and greatly emaciated. Visible gastric peristalsis appeared, suggesting duodenal obstruction.  $\alpha$ -Ray examination showed an enormously dilated stomach, a distended duodenal cap, and a really colossal degree of dilatation of the second portion of the duodenum. Several minutes elapsed before any barium passed the duodenojejunal flexure. The films of this case show a duodenal shadow approximately the size of a normal stomach. Five weeks later a successful duodenojejunostomy resulted in such great improvement that thyroidectomy could be safely done and the patient made a rapid and complete recovery. In this case it is probable that the emaciation and high degree of thyrotoxicosis (B.M.R. readings ranged from +55 to +59) were direct predisposing causes of the duodenal ileus, possibly through the mechanical effect of the loss of fat, but more probably through a profound dysfunction of the nerve supply to the duodenum causing atony.

Our interest in chronic duodenal stasis stimulated by these observations, we have sought for years for a clear-cut clinical picture resulting from lesser degrees of arteriomesenteric obstruction than were present in the 3 cases just

described. The net result of this study is an increasing degree of conservatism as to the indications for operation in what may be described as the borderline group of cases, individuals with chronic dyspepsia, absence of demonstrable pathology, and a duodenum which under fluoroscopic study shows some degree of dilatation of the second portion with reverse peristalsis and some cradling of barium. The following cases will serve to illustrate the point.

An able business executive, thirty-five years of age, had for fifteen years frequently recurring attacks of burning distress in the epigastrium with associated waves of nausea. Appendectomy had been done without relief. The symptoms were aggravated to a striking degree by fatigue and nervous strain. With the passing of years of poor health repeated and detailed medical examinations were made, with no evidence of pathology of gallbladder or peptic-ulcer type. A period of rigid ulcer treatment failed to give relief. Frequently he would be awakened at night with burning epigastric distress. He had no headaches. Attention was finally drawn to the fluoroscopic observation that with a large, well-filled duodenal cap the second portion of the duodenum filled to large size, with reverse peristalsis and some delay in the passage of barium into the jejunum. During fluoroscopic examination cramplike pain occurred at the time of the most active reverse peristalsis. Based upon this evidence the abdomen was explored, sharp angulation at the duodenojejunal flexure was found with dilatation and hypertrophy of the duodenum. Duodenojejunostomy was done and thereafter the patient had an appreciable degree of relief from dyspepsia. However, complete digestive health and comfort is enjoyed by this patient only when his constitutionally below par vegetative nervous system is freed from the effects of nervous stress and strain.

A young man, twenty-five years of age, came complaining of a similar epigastric burning distress of six years' duration, the symptoms being quite intermittent during the first four years. During the past two years, however, epigastric dis-

stress has been of daily occurrence. The relation to food-taking is similar to that of peptic ulcer and he gains relief by taking alkalis. Some associated pyrosis and vomiting and a great deal of night pain. No headaches. Previous history negative. Examination showed an individual of normal state of nutrition, normal blood pressure and blood findings. The secretory and motor functions of the stomach were normal. x-Ray examination showed what was reported to be a deformed duodenal cap, whereupon a diagnosis of duodenal ulcer was made and he gained temporary relief for some months on ulcer management, but eighteen months later he returned with the same symptoms. At that time visible gastric peristalsis indicated some degree of duodenal obstruction and fluoroscopic examination showed a normal duodenal cap, but the second portion of the duodenum filled to very large size with reverse peristalsis and delay in barium passing on into the jejunum. Upon opening the abdomen a band of adhesions was found stretched across the duodenal cap, and there were some adhesions about an apparently normal gall-bladder, but no evidence of peptic ulcer or ulcer scars, nor could any pathology be found at the duodenojejunal angle. Diagnosis, arteriomesenteric obstruction. A duodenojejunostomy was performed with complete recovery of excellent health.

Illustrating the type of case in which operation may do more harm than good, however, is the following: a spinster, thirty-seven years of age, a constitutionally below par type, fatiguing readily, with precordial pain, dyspnea on moderate exertion and right abdominal pain of many years' duration, associated with borborygmi and prodigious eructations. As is unfortunately true of so many chronic dyspeptics, she had had many operations; appendectomy, hysterectomy, an operation for adhesions, and an exploratory operation. Finally her condition was considered so unsatisfactory that upon finding x-ray evidence of a certain degree of duodenal stasis, she was again laparotomized. The second portion of the duodenum was found to be moderately enlarged and duodenojejunostomy

was performed. This was followed by several subsequent admissions on account of continuation of abdominal pain, nausea, fatigability, and other evidence of vegetative nervous system imbalance. Certainly no appreciable benefit could be credited to the various operative procedures, including the relief of what was believed to be a definite duodenal stasis. It is highly probable that the duodenal stasis in this case was a direct result of the below par state of the vegetative nervous system combined with loss of weight and that it had nothing to do with the initiation of her dyspeptic symptoms.

A similar case is that of an undernourished young society girl of nineteen, with a familial type of below par vegetative nervous system, her father being a severe migrainic. The symptom picture was one of dull epigastric pain after eating, anorexia, a spastic bowel, cold moist hands, marked fatigability, and headaches of marked migraine type.

On physical examination nothing abnormal could be found, but fluoroscopic examination disclosed a moderate degree of dilatation of the second portion of the duodenum with reverse peristalsis and lagging of barium. A very able internist advised that duodenojejunostomy be done. However, a period of bed rest in seclusion, with a high calorie diet and ample sleep cleared up the dyspepsia within a few weeks, and today, five years later, this young woman is in good health.

I believe there are many individuals with chronic dyspepsia and below par vegetative nervous system who may show from time to time such fluoroscopic findings of moderate dilatation of the duodenum, a little reverse peristalsis and possibly some lagging of barium. A great deal of conservatism should be exercised with relation to the operative treatment of this group of cases.

I wish strongly to emphasize the relatively insignificant amount of headache in the cases of genuine duodenal stasis on an arteriomesenteric basis that have come under our observation. Dr. Crile has reported good results from duodenojejunostomy in migraine sufferers having duodenal stasis, but until we possess more specific knowledge of the essential

nature of migraine, it would seem that this operative procedure should be resorted to only in cases where the x-ray findings permit of no doubt as to the existence of definite duodenal obstruction. Moderate increase in the circumference of the second portion of the duodenum with reverse peristalsis and cradling of barium may frequently be observed in normal individuals, hence the need for careful diagnostic study in the borderline cases before advising surgical operation.

## CLINIC OF DR. CLARENCE F. G. BROWN

NORTHWESTERN UNIVERSITY MEDICAL SCHOOL AND  
ST. LUKE'S HOSPITAL

---

### THE PSEUDO-ULCER SYNDROME

It is common experience that the so-called "neurotic personality" who so frequently expresses his inadequacy by a "flight into illness" reaction, presents symptoms referable to the gastro-intestinal tract. The most common symptoms complained of by this type of individual are vaguely described by him as "stomach trouble." Indefinite epigastric distress, such as bloating, an uncomfortable sensation of fullness, particularly after eating, sensations often called by the patient "pain" but on direct questioning rarely found to be true painful sensations, are usually the most prominent complaints. Occasionally nausea and vomiting may occur. Not infrequently this type of patient who experiences some degree of nausea induces the vomiting by insertion of a finger into the pharynx. On rare occasions, as a result of severe retching, fresh blood may appear in the vomitus giving rise to exaggerated alarm on the part of the patient, and may cause the examiner to consider seriously the possibility of a definite peptic ulcer. The neurotic patient suffers commonly from constipation and is often an habitual user of laxatives. Sometimes diarrhea occurs, often of the "mucous colitis" type, a popular fad of a few decades ago. Such signs and symptoms may be considered as "pseudo-ulcer" syndrome.

While the existence of such an entity has been questioned by some, it seems quite definite that there are a certain number of patients presenting a second type of "pseudo-ulcer" with characteristic subjective manifestations typical of peptic

ulcer, in whom repeated careful roentgenologic and laboratory studies fail to reveal any positive objective findings. The latter group has the perfect foundation for ulcer, but the "gastric defense mechanism"<sup>1</sup> is able to meet the situation despite pylorospasm and "ulcer" distress. The patient has all the symptoms, but no ulcer. The first group also move into the second group after they have better learned the proper symptoms of ulcer from doctors, newspapers, ulcer-bearing friends, and drug store pamphlets. The first group more properly would fall into the general group loosely called "nervous indigestion." When the pseudo-ulcer patient is "pressed" too hard by environment, overly fatigued, exposed to infection, or forced to eat a very irritating diet, he may eventually develop an organic ulcer.

Eusterman and Balfour<sup>2</sup> have tabulated the results of statistical studies by Blackford,<sup>3</sup> Foster,<sup>4</sup> Davis and Vander Hoof,<sup>5</sup> indicating the frequency of the various causes of dyspepsia encountered in hospitals and private practice. Their figures, representing a total of 7300 cases with symptoms of gastric disturbance, indicate that purely functional causes are responsible for 22 to 25 per cent of the complaints. Actual organic disease of the stomach or duodenum accounted for approximately 14 per cent.

A more recent study by Dwyer and Blackford<sup>6</sup> tabulating the results of a study of 3000 cases, showed that organic conditions of the stomach or duodenum were found in only 15 per cent of the cases. Reflex disturbance resulting from gall-bladder pathology was found to be the most frequent organic cause of indigestion.

In a consecutive series of 15,000 patients with chronic dyspepsia examined at the Mayo Clinic, Alvarez<sup>7</sup> reports that a total of only 18 per cent of patients' digestive disturbances were the result of organic disease of the stomach or duodenum.

It is evident, therefore, that from the standpoint of both diagnosis and therapy, only a relatively small percentage of patients with chronic dyspepsia have organic changes of the

stomach and duodenum. Some 60 per cent can be accounted for on the basis of reflex disturbance resulting from pathology elsewhere in the gastro-intestinal tract or gallbladder. Approximately 25 per cent fall into the functional group and may or may not present the "pseudo-ulcer" syndrome.

Before diagnosing a case of "chronic dyspepsia" as of functional origin in this or any other clinic, it is paramount that all possible organic causes, reflex or otherwise, be definitely ruled out. Careful objective study of the gallbladder, appendix, and entire gastro-intestinal tract are essential. In too many instances the patient is either diagnosed as having a peptic ulcer without objective evidence, or unwarrantedly declared to be just "another extremely nervous individual."

At best, the symptomatology of pseudo-ulcer is extremely variable. Vague, dull, aching pain in the epigastrium, poorly localized, usually brought on by emotional stress and strain, an irregular relationship to the intake of food, and not relieved by ordinary medical measures successful in the treatment of true peptic ulcer, is the characteristic history. Associated signs and symptoms may or may not be present. In some cases, there is nausea and vomiting. (Perhaps since the widespread use of the gastroscope there may be a tendency to call this picture by its old all-embracing name, "gastritis.") Localized tenderness is usually absent on palpation of the epigastrium, a finding which occasionally tends to differentiate the condition from true ulcer. During periods in which the patient is free from emotional strain, he is liable to forget all about previous gastric complaints, exaggerating excellent health until he is confronted again by an emotional or psychological problem, the solution of which he finds too difficult. As a result, he again resorts to the "flight into illness" reaction, as expressed by his gastro-intestinal symptoms. Examination of the patient rarely reveals any definite findings. The patient may show exaggerated reactions to abdominal palpation, displaying anxiety and fear.

The patients whom we present to you today are typical of the first type of functional "dyspepsia," in whom the

symptom complex somewhat simulates that of peptic ulcer. Four out of the 5 have been diagnosed as peptic ulcer patients at other institutions.

**Case I.**—S. B., a white male, aged thirty-two years, was admitted to the St. Luke's Hospital Out-patient Department on December 2, 1931, complaining of a heavy feeling in the epigastrium occurring periodically for two and one-half years, 40 pounds' loss in weight over this period, belching, and constipation. There was also a sensation of diffuse abdominal discomfort of indefinite description. The epigastric discomfort was relieved by the taking of food, but only at times occurred with relation to meals. Cathartics were resorted to regularly in order to induce bowel movements. The remainder of the history and physical examination was negative. There were no positive laboratory findings. In general, however, the patient appeared weak and pale and seemed to appear to feel much worse than most ulcer patients. A tentative diagnosis of spastic colitis was made, and the patient was placed upon a bland diet, antispasmodics, and kept under observation. He ran an irregular course without much subjective or objective improvement, continued to lose weight, and was referred to our clinic August 17, 1932. Frequent aspirations and analyses of the stomach contents were begun at this time. The record of free hydrochloric acid values thus obtained may be seen in Fig. 11. A complete roentgenologic study of the gastro-intestinal tract revealed only a spastic duodenal bulb with no constant deformity. In view of all findings, this patient was studied as a non-ulcerbearing individual but was started upon gastric mucin, hourly feedings, antispasmodics, and subsequently received therapy similar in character to that prescribed for patients with peptic ulcer in this clinic. During our observation, the patient had remained approximately the same objectively, as indicated in the chart (Fig. 11). His epigastric discomfort has decreased markedly during the past year, and at present his chief complaint is constipation. This has been adequately controlled by metamucil. It is significant

that no duodenal deformity has been apparent in any of the  
 twenty rechecks. He has many of the proper symptoms, but

apparently cannot develop an ulcer. We consider such a patient as being a potential ulcer-bearing individual.

This illustrates how a patient who apparently had no peptic ulcer did not improve for years until the management included attention to the strong neurogenic and psychogenic factors. He was able to return to work and was one of our most grateful patients.

**Case II.**—L. A., a white male, aged forty-eight years, was admitted to the neurological service of St. Luke's Hospital May 25, 1933, complaining of dizziness and nervousness since the fall of 1932 following an appendectomy, the loss of a job he had had in a laundry for twenty-one years, and eviction from his house. The patient states that he was very depressed at the time, but felt somewhat better now. On questioning, the patient revealed that he was extremely unhappy at home, had a nagging wife, and that in the course of their frequent disputes, his sons would usually take her side. A diagnosis of psychoneurosis was made, and the patient was placed on sedative medication. On November 19, 1933, the patient was referred to our clinic complaining of dull headaches, a burning sensation in the epigastrium radiating to the neck, marked flatulence, constipation, hemorrhoids, dizziness, nervousness, shooting pains and weakness in the arms and legs, and in addition stated that he thought he was becoming impotent, that he might have a goiter, that he might have prostate trouble, and that he had no resistance to colds. The epigastric discomfort occurred anywhere from one-half to one hour after eating, and was sometimes accompanied by nausea and vomiting. He attributes the latter difficulty to his wife's poor cooking. By and large, his greatest complaint was his wife, whom he said was not affectionate and failed to understand him despite twenty years of married life. In 1923, the patient had a tonsillectomy and adenoidectomy, in 1930, gonorrhea, and in 1932, an appendectomy. Hourly feedings were prescribed and psychotherapy administered. On December 4, 1933, the patient was referred to neurology, and at

this time complained that his wife and two sons "had taken everything from him and treated him like a dog." He now had to eat cold cereal for breakfast because his wife refused to get up and cook for him. Following this meal he would usually retire to the outdoors to vomit it up. The patient stated that he had no desire to work, because if he earned any money, it would have to be used to pay rent for his wife. He further expressed the conviction that his gonorrheal infection in 1930 followed the return of his wife from a six months' trip to Michigan. The subsequent history consisted chiefly of accounts of his marital difficulties. On one occasion the patient presented himself at the clinic with a black and blue arm following an effort to guard himself when his wife tried to kick him in the testicles. Following this episode, the patient was advised to become a sailor but, as with other psychotherapy in this case, met with no success. Seventy gastric analyses during various types of management were obtained on this patient. The results showed an almost persistent hyperacidity. However, repeated roentgenologic examinations of the gastro-intestinal tract failed to reveal any pathology. When we recommended that the patient go to work, he demurred, became aggravated, and stopped attending our clinic.

**Case III.**—E. W., a white male, thirty-one years of age, was admitted to the St. Luke's Hospital Out-patient Department May 8, 1931, complaining of convulsive seizures of two years' duration, epigastric discomfort of seven months' duration, and the swelling of a gland in his neck of one week's duration. The patient stated that the epigastric discomfort occurred on the average of several times a month and would sometimes last as long as two hours. Usually the distress would start between one and two hours after meals. Frequently there was an accompanying nausea, but no vomiting. On physical examination the patient was found to have a slight fever, cervical lymphadenopathy, and a palpable thyroid. A diagnosis of infection of the right tonsillar stump was

made, and the patient was treated accordingly. He was subsequently referred to neurology where a diagnosis of idiopathic epilepsy was made. May 17, 1933, the patient was referred to our clinic. At this time, he complained of dull epigastric pain, continuous in nature, and unrelated to the taking of food. The patient further complained of belching, flatulence and constipation. Repeated gastric analyses revealed no positive information. The roentgenologic studies of the gastro-intestinal tract were likewise negative. The patient was placed on hourly feedings and antispasmodics, and obtained considerable relief. At the present time, the patient is on a bland dietary management in conjunction with antispasmodic medication. He is still subject to periodic recurrences of distress, at which time hourly feedings are again prescribed. This patient illustrates the typical "flight into illness" reaction and responds only to dietary and psychotherapeutic management.

**Case IV.**—N. L. J., a colored male, thirty years of age, was admitted to the St. Luke's Hospital Out-patient Department, January 27, 1929, complaining of epigastric distress, regurgitation of food after eating, and upper right quadrant pain referred to the right shoulder. The patient stated that he began to have "stomach trouble" about nine years ago and was treated at this time for a period of five weeks at a large Baltimore hospital. He was given powders and a liquid medicine, the exact nature of which he did not know. He never was entirely cured, and the distress recurred at intervals varying from one week to one month since that time. For the past four months, the pain has been present following every meal and has been extremely intense at night. Usually the distress begins as a heavy feeling in the region of the umbilicus, and then radiates to a small area in the epigastrium. It then travels to the right upper quadrant and finally to the right scapula. On some occasions the pain begins while the patient is eating, but usually starts between fifteen minutes and one hour after the meal. The patient states that the

distress has made him feel very nervous and that for the past three months he has been unable to work. For about two years he has regurgitated sour material after eating. In recent months he has been taking various powders and patent medicines, but has been unable to obtain relief. The physical examination of this patient was not significant. Blood Wassermann and Kahn tests were found positive, and the patient was placed on antiluetic therapy. A roentgenologic study of the gastro-intestinal tract revealed a highly spastic colon and a deformity of the duodenum which was not constant and interpreted as being a highly questionable duodenal ulcer. Sippy management was instituted, and only slight improvement was noted. Mucin therapy was tried in August, 1932, following which the patient began to show marked subjective relief. The right upper quadrant distress was relieved by keto-cholanic acid.\* The routine gastric analyses performed on this patient were not clearly indicative of organic pathology.

This patient definitely falls into that group in which there are not sufficient positive objective findings to make an out-and-out diagnosis of peptic ulcer. The history itself was atypical. The gastro-intestinal condition did not improve on antiluetic therapy. We feel that such a case comes under the pseudo-ulcer classification, and should be carefully watched, as well as being given ulcer therapy.

Case V.—J. B., a white male, forty-two years of age, was admitted to the St. Luke's Hospital Out-patient Department, December 28, 1932, complaining of dull epigastric pain, unrelated to the taking of food, pain in both lower quadrants, weakness, nervousness, and loose watery stools. The distress first began four years ago and has continued more or less regularly since that time. On physical examination the thyroid was found to be slightly enlarged but soft, the skin moist, and the reflexes hyperactive. There was a hypertension and tachycardia. A basal metabolism test was ordered, but was

\* Not available as yet

found to be within normal limits. A complete roentgenologic study of the gastro-intestinal tract revealed no pathology. Hourly feedings and antispasmodics were prescribed, but the patient still continued to have indefinite epigastric distress. In February, 1934, the patient stated that he had a sharp cramplike pain beginning in the epigastrium and localizing in the right lower quadrant. Physical examination revealed slight rigidity over McBurney's point, and this information, together with the finding of an elevation in the white blood count, indicated a diagnosis of appendicitis. An appendectomy was done, typical pathology found, and the patient made an uneventful recovery. The epigastric distress, however, continued. A second roentgenological study still failed to demonstrate any abnormal findings. Late in 1935, the patient underwent a period in which he had considerable marital and family difficulties in addition to financial worries. The epigastric distress increased in severity, and this time the roentgenologic study demonstrated a definitely deformed duodenal bulb. The patient is now on our routine ulcer management with animal mucin and metamucil, and is beginning to show marked improvement.

This patient apparently can be classified as an atypical "pseudo-ulcer" type of individual who finally developed an ulcer while under our observation.

#### DISCUSSION

Under our designation of "pseudo-ulcer" syndrome are to be found two main groups. The first may be considered "psychogenic," occurring in the familiar psychoneuroses. The second group we have designated "neurogenic," implying a more definite involvement of the physiology of the gastro-intestinal tract as a result of interference with the nervous mechanism as stated above. A sharp distinction cannot be made between these 2 groups in many instances, due to the fact that associated with the "psychogenic" gastro-intestinal disorders and attributable to the physiologic changes resulting from emotional factors, certain disturbances of gastro-intes-

tinal function actually occur. More typical of the neurogenic group are those instances of pseudo-ulcer syndrome which arise reflexly from pathologic conditions of neighboring organs. In this latter group, attention must be paid chiefly to these sources.

The physiologic alterations of the gastro-intestinal tract occurring as a result of abnormal emotional reactions must be properly emphasized. It is well known that the neurasthenic patient frequently may show spastic phenomena and hyperirritability of the gastro-intestinal tract. Therefore, although the basic cause of the patient's disturbance may be psychogenic, these bodily changes associated or arising secondarily, must be looked upon as physiologic problems, "neurogenic" in origin, and merit due consideration in the plan of therapy. Although psychotherapy should constitute the chief therapeutic procedure, this must be supplemented by the common sense use of dietary and medical measures commonly employed in the treatment of organic gastro-intestinal tract disease. Thus, frequent, small, bland feedings, with the judicious use of gastro-intestinal tract sedatives as indicated, have a definite place in the handling of such functional gastric disorders.

The "pseudo-ulcer" patient should be so managed as to enable him to overcome the neurogenic factors tending to produce peptic ulcer. His mode of living must be so altered as to shelter him from the difficult environmental stimuli received in every day life. With some private patients this may be accomplished by a vacation trip, but they must be prepared emotionally for return to their original environment. If the former course is impractical, as it was in our clinic patients, their attitudes must be so molded that they may adjust to the untoward situations occasioned by their anxiety. Stimuli related to poverty, starvation, insecurity, frequent evictions, etc., should be made to be ineffective except in so far as the patient is able to control the circumstances. The inadequate person oftentimes is not making all possible use of his available personality. With treatment a much more adequate "carefree" or anxiety-free personality may result.

A convenient point of view, easily grasped by the patient, is that one must recognize the fact that the world is normally the way it is—trouble, trial, lack of appreciation, meanness, cupidity, injustice, or ingratitude—all being attributes of human character. He should be made to appreciate that, after all, it is the only world we have. Encouragement, suggestion, reassurance, together with methods to overcome chronic fatigue, eventually change the visceral reflex threshold controlling pylorospasm, peristalsis, etc. It is generally agreed that many of the physiological changes are secondary to, or actually a part of, emotion, and the residual or more complicated histological changes are due to many repeated stimuli.

The success of such a method of treatment depends upon a favorable relationship between the patient and the doctor *i. e.*, transference. Talks with the patient are a possible means of giving him an insight into his maladjustment and effecting a possible change in his personality, enabling him to better meet the emotional problems. In some cases, simple methods do not suffice, and the patient is unimprovable. Such cases definitely require psychiatric consultation. Above all, the patient should never be told "not to worry." Such advice has probably been given by the patient's family and would-be friends for years before he sought medical attention. The patient should worry just enough to get along in the world and follow his management.

## CLINIC OF DR. JESSE R. GERSTLEY

MICHAEL REESE HOSPITAL

---

### THE TREATMENT OF PNEUMONIA IN CHILDREN

THIS boy, aged ten years, has just recovered from one of the severest attacks of pneumonia I have ever seen. For a week before the onset he complained of being tired, languid and not feeling well. Being a child who adopted this ruse occasionally in order to avoid school, this aroused no particular concern. His parents noted that he looked well, that his morning and evening temperature were normal, and sent him protesting on his way. On the morning of December 1st, he awoke with a chill, vomiting, and fever of 103° F. He complained somewhat apathetically of headache and dizziness. Within a few hours the temperature rose to 106° F., and his pathetic, pinched face and dazed demeanor showed him to be the victim of a highly virulent infection. To quote his mother, "He's sicker than I have ever seen him. He's really sick this time."

The vomiting continued so perniciously during the day that not even a teaspoonful of water was retained.

The following morning found him slightly cyanotic, still vomiting and very toxic. Some impairment of resonance in the right lower lobe posteriorly, with a diminution of breath sounds, revealed the diagnosis. Accordingly he was rushed to the hospital and put in an oxygen tent.

On admission his temperature was 106.6° F., pulse 136, respiration 36; white blood count 23,000, with 85 per cent polymorphonuclears. He tended to be apathetic but was reasonably rational when aroused. His cough was not particularly troublesome. Other than the chest involvement and dilatation

of the wings of the nose on respiration, physical findings were negative.

Dilatation of the wings of the nose on respiration is one of the most valuable signs in the diagnosis of pneumonia in children. Many times the physical findings do not become manifest for some days and this sign furnishes the first valuable clue.

At times he complained of pain in the right lower abdomen. A scar, however, saved us the difficulty of ruling out appendicitis.

He was now so toxic from the combined effects of infection and dehydration that he was given an intravenous drip of 225 cc. of equal parts normal saline and 10 per cent glucose, followed in two hours by an additional 350 cc. of 10 per cent glucose. The fluid and carbohydrate temporarily diminished the toxicity and gratified his pathetic need of water.

On the afternoon of the third day he became intensely delirious. The oxygen tent filled him with wild fears, the noise of the motor terrified him, and he sat up and struggled frantically to escape. In desperation we took the tent away and quieted him with a hypodermic of  $\frac{1}{12}$  grain of morphine.

I consider morphine one of the most valuable drugs in such a crisis. No matter what one reads of its depressing effects, the first essential in the treatment of such a severe illness is quiet. In my experience morphine in doses small but enough to quiet the patient is invaluable, and really acts as a stimulant. Next to morphine ranks codeine in sufficient dosage.

Following the morphine he became much quieter, with a slight drop in temperature, pulse and respiration, but within a few hours the fever was back to 105° F. and he was complaining of pain in his left ear. There was some tenderness on pressure and the drum was dull and slightly bulging.

The fifth day in the hospital was a severe one. At the dreary hour of four in the morning when life forces are at their lowest, the little boy had a severe chill lasting about fifteen minutes, followed by cyanosis, thready pulse, marked restlessness and delirium, repeated emesis, and abdominal disten-

tion. Cough for the first time became distressing. He was replaced in the oxygen tent and given 2 grains of caffeine sodium benzoate hypodermically. In the afternoon with fever of  $106^{\circ}$  F. his condition seemed so critical that he was given a transfusion of 120 cc. of whole blood intravenously into the ankle vein, followed by an intravenous drip of 300 cc. of Hartmann's solution.

One of the most valuable advances in the treatment of any sepsis combined with dehydration and starvation has been the use of the intravenous drip, and this has been greatly facilitated by the technic devised by one of our former interns, Dr. M. L. Spivek.<sup>1</sup> Every one of you should make it a point to read the article and familiarize yourself with the technic.

A portable x-ray showed involvement of the entire right chest, the shadow being somewhat denser in the right upper lobe. Unquestionably the chill followed the involvement of this lobe. Whenever a chill occurs during the *course* of an acute infection in a child, look out for trouble. Examination showed bronchophony and bronchial breathing all through the upper part of the chest, anterior, posterior, and in the axilla.

On the morning of the sixth day at 4:30 the patient again suffered collapse, with temperature dropping to  $102^{\circ}$  F., cyanosis, chilly sensations, and a weak pulse. He complained of dyspnea and nausea. In the afternoon with temperature back at  $106^{\circ}$  F., rapid thready pulse, cyanosis, abdominal distention, and with vomiting still preventing any fluid retention, he was given another blood transfusion of 150 cc. into the ankle vein, followed by intravenous drip of 700 cc. of Hartmann's solution containing 50 cc. of 50 per cent glucose. Following this, the little boy became definitely better. The temperature, pulse and respiration remained unchanged, but his appearance was definitely less toxic. Two days later his temperature dropped to  $102.6^{\circ}$  F. but by afternoon it was back to  $104^{\circ}$  F.

Look out for these pseudo-crises! In the early days of my practice I used to be fooled by them. A patient is never

<sup>1</sup> See M. L. Spivek, Simple Method of Transfusion for Infants and Children, *Am. J. Surg.* 7, 1934 (August), 1935.

out of danger unless the temperature has dropped to subnormal. A drop to anywhere above normal may be of no significance. It may mean that the disease is going to terminate by lysis. But be on the alert for complications.

From this time with one exception there was continual improvement and the temperature dropped slowly by lysis to normal on the thirteenth day. With the steady improvement, the oxygen was reduced daily about 10 per cent, from 50 to 20, and he was taken from the tent.

You remember that on the fourth day he complained of pain in the ear, and examination showed some bulging of the drum. He was so desperately sick that I did not want to subject him to one bit of further strain. Anyway, I am perhaps ultraconservative as regards puncture of the ear drum in children. In my experience harm rarely results from waiting unless the condition is most acute. In this case the pain disappeared after a few hours. However, the findings remained and even after he became perfectly rational he seemed hard of hearing. At this time the ear was opened, the pus evacuated, and within three days this entire complication had cleared up. I am quite sure that it healed much more rapidly than it would have, had it not been handled so conservatively.

This case is of particular interest because it illustrates the type of disease confronting us at the present. It illustrates the insidious prodromes, the difficulty of an early diagnosis, and a common complication. It illustrates modern methods of treatment without which I believe we would have been unsuccessful.

In this clinic I am going to limit my discussion to that of treatment. I should like to speak of the various pathological, bacteriological, and clinical types of pneumonia; the onset often so insidious; the frequent difficulty of early diagnosis; the critical judgment and experience required at times to differentiate the early stages of the disease from appendicitis or to determine the onset of a complicating appendicitis or peritonitis, and the common complications such as otitis and empyema but time will not permit.

## TREATMENT

**Prophylaxis.**—Is there a prophylactic treatment? There is no question that since the World War the common type of pneumonia has changed. No matter what the organism, the clinical course, especially in the treacherous and insidious onset, smacks of influenza. You usually get a history of a mild fever for a day or two, then a day of normal temperature. The mother or inexperienced physician reassured by the absence of fever relaxes vigilance. Then on the third or fourth day comes a dramatic recrudescence and the patient has pneumonia. Such is usually called a relapse. I am inclined to think it is the normal picture and that during the present years these mild upper respiratory infections should be treated as if the ordinary course of the infection were a day or two of fever, a day of normal temperature, and a day of recurrence of fever. It is just here that we must practice our prophylaxis.

Whenever there is much pneumonia around, watch out for this first day of normal temperature and don't relax your vigilance until the one day has been extended to two. I tell parents that during the first day of normal temperature they should observe precautions identical to those used during the time of acute illness. This means absolute rest in bed, no excitement, no visitors, and a light diet. If available, a bedpan should be used, and if this is impossible the child should be carried to the toilet, and before being taken from bed should be dressed in stockings, slippers and a robe to avoid chilling. By this procedure I have relieved myself of qualms of conscience that used to come at the beginning of this period of new experience, when the prodromal symptoms were overlooked.

**Active Treatment.**—In discussing the treatment of pneumonia I will first discuss the conventional treatment, and then discuss the special procedures which I think were responsible for saving the boy's life.

**Rest.**—Once the disease has been recognized, the all-important treatment is *rest*. I cannot emphasize this too strongly. And when I say *rest*, I do not mean rest conversationally or rest on the patient's record, but *complete physical and mental*

*rest for the patient.* Far more patients are lost by too much rather than too little treatment. Certainly every case does not need hospital care. One must always balance the disadvantage of moving a patient from his home, with the advantages of hospital facilities. I rarely advise hospitalization unless there is a very definite indication.

**Nursing.**—Pneumonia is still a disease in which the basic treatment is one of nursing. The nurse must be instructed to be quiet, unobtrusive, and to disturb the patient as little as possible. Many nurses are overzealous in their efforts to keep the bed in order, to keep the patient clean, and to wear him out with a toothbrush. The physician must watch the nurse carefully in all such details. The nurse should permit no visitors, and should make every effort to keep parents and relatives out of the sick room. Needless to say, the room should be well ventilated and this must be done even at the expense of the nurse's comfort. While the decade is over where we advocate unusually low temperatures, there is no question but that the patient is more comfortable in a moderately cool room.

**Fever.**—We are not as concerned about fever as we used to be. For a temperature over 103° F. I usually order small doses of acetylsalicylic acid from 1 grain in an infant to 5 grains in a child of six or over. A cool cloth to the head and a tepid sponge may make the patient decidedly more comfortable, but in giving the sponge do not overdo it; be careful that your little patient is not exposed to any possible chilling. The *priessnitz* (a wet cloth wrapped around the chest and enclosed in oiled silk) may quiet a delirious patient. It must be kept moist, however, or it becomes an extra blanket. The added weight to the chest also may oppress the patient. In this respect let me speak of my particular hobby, now a protest of twenty years' duration, against the universal practice of pinning the infant's shirt to the diaper. Just at the time when the child is using every thoracic and abdominal muscle in his struggle against asphyxia, any additional handicap to these muscles may turn the tide.

In former years a temperature of 105° F. was considered

an absolute indication for vigorous treatment. I do not think this holds true in a child. Indeed, I have entirely changed my tactics, and at these extreme temperatures rather fear the active hydrotherapeutic procedures. At 106° F. the child may complain of being chilly; the extremities cold. Under such circumstances the cold sponge may do more harm than good, particularly following a chill. A cloth wrung out in warm water and applied to the chest and hot water bags to the feet, may be more advantageous than cold applications.

Perhaps the best therapy for fever is after all giving the patient plenty of fluid, so that he has an abundant supply to drain the heat from his body through perspiration and respiration.

**Acidosis.**—This is recognized by finding acetone in the urine. Some men give various alkalis. The most effective therapy is plenty of carbohydrate and Hartmann's solution, intravenously if necessary.

**Tympanites.**—Tympanites in itself is a grave sign. It is a manifestation of toxic ileus. By pressing upward on the diaphragm it decreases the available air space in the thorax and presents an additional handicap to the patient. One may reduce tympanites by mild cathartics, such as magnesium citrate or milk of magnesia. As a rule, I find cathartics are only of temporary assistance and sometimes seem to be followed by increased distention. They also tend to upset the stomach. Equally satisfactory results can be obtained by a simple glycerin suppository or better yet, by the 1-2-3 enema, consisting of 1 ounce of glycerin, 2 ounces of magnesium sulphate and 3 ounces of water. Pituitrin may be of value, and at times I have thought that I obtained results by injecting from  $\frac{1}{2}$  to 1 ampule of pituitrin into the abdominal cavity.

When tympanites is present, milk sometimes increases the discomfort. The digestion of milk is facilitated by peptonization, the addition of acid, or dilution with carbonated water. However, when there is much abdominal distention I prefer as little milk as possible. Weak tea or fruit juices do better.

The patient may also be made somewhat more comfortable

by propping him up. Here the thoracic viscera help weigh the diaphragm down and to some extent combat the upward pressure from the abdomen.

**Specific Therapy.**—The drug, optochin, which was introduced as a specific has, as far as I know, not lived up to the original claim. I have had little experience with it, and believe it is considered dangerous by some. There are, of course, various sera to be obtained and in desperate cases one may resort to these. Certainly favorable results have followed the use of Type I antipneumococcus serum, and the concentrated serum of Felton. I have had little experience with these because my recent interest has been in convalescent serum.

**Stimulation.**—It has always seemed to me that adrenalin given hypodermically in doses of 2 to 5 minims is the most effective drug in maintaining blood pressure. I usually combine it with camphor and oil which is a good emergency stimulant. Some men have gone back to strychnine, while caffeine sodium benzoate is again returning to vogue. I have recently come to have more confidence in blood transfusion than in any medication for the support of failing circulation and blood pressure.

**Diet.**—By careful supervision of the diet we certainly can facilitate the ultimate recovery of the patient. The indications to be met are:

(a) The diet must facilitate recovery from the initial vomiting, and protect against further gastro-intestinal disturbance.

(b) Following cessation of the vomiting the diet must contain sufficient fluid.

(c) It must contain nutriment, especially carbohydrate. The latter is of particular value in sustaining the circulation and in overcoming acidosis.

(d) As soon as possible the diet must contain increasing caloric and nutritive elements.

**First Day.**—For the first twenty-four hours it is safer to give the patient nothing but hot weak tea, with sugar and lemon. I prefer no milk. If the vomiting ceases, the child may also have a little water and some hot clear soup. It is

always more advisable to offer small quantities of fluid frequently repeated. Larger amounts tend to nausea and by overloading the stomach interfere with respiration.

*Second Day.*—As soon as feasible we meet two indications: maintaining body fluid and supplying sufficient carbohydrate to sustain the circulation.

I think we have been remiss in estimating the amount of fluid required during an acute illness. This youngster after the first day in the hospital (during which he took only 9 ounces) took 2 quarts daily during most of the acute stage in addition to the blood and saline transfusions. Whether a child is receiving sufficient fluid is indicated by the specific gravity of the urine.

Vomiting having ceased, one might offer increased quantities of fluid; water, orangeade, lemonade, iced tea, ice pellets, ices, fruit juices; and even nutriment as milk, and possibly small quantities of malted milk, cereal, jello, custard, ice cream, toast, cracker and baked potato.

The advantages of ice pellets and ices are that though taken in small quantities they tend to lower the temperature.

In an infant the formula, and in an older child the first whole milk feeding should be diluted. Equal parts whole milk and carbonated water make a pleasant beverage for a child of over a year.

Any cereal may be used depending upon the child's habit and taste. Pabulum of Mead Johnson and Company may be the most easily digested. I prefer it prepared with water rather than milk during the height of the illness, and add only half milk instead of whole milk on the first serving. Of course if the attack is at all severe, the patient should take nothing but fluids for several days.

Carbohydrate in adequate amount is life-saving. It is both a food and a circulatory stimulant. It is urgently demanded when acetone is found in the urine. It can be given as sucrose, lactose, glucose, or the malt and dextrin preparations. The maximum quantity should be added to all food and liquid without interfering with the taste. I like sucrose the least

because it is sweetest. Lactose or the more soluble beta-lactose has the advantage of being less sweet and of favoring a gram-positive flora which is not gas-producing. Glucose is sweeter but requires no digestion. In every case the problem is individual and the child should be offered the carbohydrate of which he takes the most. The fruit juices are often the best vehicles; grapefruit juice is especially advantageous. Children usually will not tolerate carbohydrate in water or milk, while they will in tea. Under no circumstances should a basic essential food be tampered with in a way to make it unacceptable. Each child should be treated individually and here is where the common sense of the nurse is of utmost importance. For a child in an oxygen tent lollipops are invaluable. They not only furnish carbohydrate, but also a thoroughly familiar and enjoyable contact with the outside world.

In the more severe cases when vomiting or dyspnea prevents taking adequate quantities of fluid, the intravenous drip is life-saving. This may be given as normal saline, 10 per cent glucose solution, saline mixed with equal parts of 10 per cent glucose, or Hartmann's solution with glucose in those cases tending toward acidosis. The drip should average about 60 drops a minute. One must remember that while glucose is life-saving, the more glucose, the more viscid the fluid and the slower the administration. The intravenous drip is a godsend; it supplies the life-giving necessities without overwhelming the circulatory system with sudden large increases in water and carbohydrate. In giving fluid by the ankle veins the foot must be exposed for several hours. I have a feeling that a patient with a temperature of 106° F. would not voluntarily have his foot out of the blankets. I think it is of great importance that the extremity be kept warm with hot water bags or an electric pad during the intravenous administration. However, look out for burns. The skin during this period is very susceptible and has a low resistance to heat.

There is, however, a possibility of giving too much fluid. Vomiting which is supposedly toxic may be a defense against overloading the circulatory system. Certainly the response in this case shows that tolerance was not overstepped.

**Convalescence.**—As soon as a child is convalescing he will automatically want more food, and in my experience meat is one of the most desirable additions. I have found that small quantities of round steak ground are particularly acceptable and easy to digest. However, the nurse cannot conveniently feed the child in an oxygen tent. Under such circumstances do not stand on formality; be human. When the weak trembling little hand cannot carry a fork or spoon to his mouth push the plate of meat into the tent and tell him to use his fingers. The smile of gratitude you receive will amply compensate for the breach of etiquette.

As a rule I do not prescribe egg until the child specifically desires it.

The advances in therapy besides the intravenous drip which were responsible for saving this child's life I think are oxygen and blood transfusion.

**Oxygen.**—Oxygen is indicated whenever the body is laboring under an oxygen deficiency. There is nothing specific about oxygen other than that it keeps the blood aerated, and to that extent relieves circulatory embarrassment. Formerly, I used to withhold oxygen until the patient was cyanotic. Now, I believe it is of value if given in sufficient time to prevent any asphyxia. This does not mean that the child with the ordinary pneumonia, who is running an average course, who is comfortable and who shows no respiratory or cardiac embarrassment needs oxygen. But at the first indication of any air-hunger, I prescribe it.

We usually start with 40 or 50 per cent, and then as the disease becomes less severe, gradually decrease to about 20 per cent before removing the tent. There are advantages and disadvantages to the tent method. Many of the tents are old-fashioned and small and the blast of chilled oxygen focuses on one spot of the chest; they require expert supervision and constant manipulation; they make examination of the patient very difficult; they make it almost impossible for the nurse to bathe and sponge the patient, and they are particularly annoying to irrational patients. Patients in a tent complain

particularly of their lonesomeness and isolation. This is felt even by young children, who in a vague way are forlorn at their isolation from the rest of the world. Putting into the tent a familiar plaything may be almost life-saving. To be able to touch affectionately a beloved doll, or woolly animal or well known book may bring peace to the harried sufferer.

A further objection to the tent is that any careful physical examination requires removal from the tent and that many a nurse in her zeal at making up the bed in the morning, ruthlessly takes the patient out without regard for the abrupt changes in oxygen tension and the sudden demands put upon the circulation when the child is plunged from an atmosphere of 50 per cent oxygen to that of ordinary air. I make it a rule that once in an oxygen tent the patient should be left there. I resent the abrupt changes of environment which must be a great shock to a very sick patient. I instruct the nurses to let the making of the bed go, and do the best they can without disturbing the environment of the child.

On the other hand, once in a modern tent the patient is comfortable. The new tents let oxygen come in from the top gradually and have done away with the draught of chilled air focused on one spot. When handled efficiently, the air is pleasantly cool, moist, and is pleasing to the patient. The oxygen content remains constant, and can be controlled at will.

One must not forget that the temperature in the tent may be considerably cooler than in the outside room. The thermometer should be watched, and the child may need extra covering around the chest.

It seems to me that many of the advantages without so many of the disadvantages might be obtained by oxygen through a nasal catheter. I have had little experience with this but plan to try it in the future. The oxygen can be cooled and moistened just as with a tent, and as most pneumonias occur in winter, the air of the room can be made of any temperature pleasing to the patient. This procedure would have the advantages of economy compared to the exorbitant cost of the tent, and at the same time would permit examination of

the patient, therapeutic procedures and nursing technic without changing the amount of oxygen inspired.

In bronchopneumonia, when the actual accumulation of secretions in the lungs threatens asphyxia, I have found raising the foot of the bed a valuable procedure. Gravity helps drain out the secretions and also gives mechanical support to the coronary circulation.

**Transfusion.**—For failing circulation rather than resorting to drugs, I am using blood transfusion more and more. The subject of shock has interested me ever since my intern days. At that time surgical shock was pointing to the vasomotor center. I learned that medical men were beginning to suspect a similar mechanism in medical shock. My first experiments were with the effects of posture upon blood pressure. During these twenty years medical therapy has consistently adopted every contemporaneous device which might be used to maintain systemic and coronary blood pressure. At present shock is supposedly due to an escape of fluid from the blood vessels into the tissues. Colloidal solutions will remain in the blood vessels longer than ordinary fluids. Salt solutions are of value in combating anhydremia but quickly ooze through the blood vessels and are of no permanent value. Blood, on the other hand, due to its colloidal property will presumably remain longer in the vessels. I sometimes suspect that the value of those antitoxins which are used in large quantities may be to some extent due to this colloidal quality. In this boy 120 and again 150 cc. of blood were given. In addition to the support of the circulation, the blood maintains nutrition and offers an additional reinforcement of leukocytes and red blood cells to replace those destroyed. I believe following a transfusion the appetite unquestionably increases. Then again it is very possible that in a hit or miss way, one may use a donor whose blood contains antibodies. At any rate, I am convinced that transfusions, if given properly and in not too great amounts, are of life-saving value in the severer pneumonias. There is the theoretical danger of cardiac dilatation and overload. I have never seen this occur when the proper precautions as regards technic and quantity were observed.

**Convalescent Serum.**—I cannot close this clinic without a word about convalescent serum. For some years I have been using it in the wards, trying to make up my mind whether it has any value other than that of blood transfusion, and I must confess it is most difficult to form a conclusion. The difficulty at arriving at scientific truth is due to the fact that the present-day pneumonias may be due to so many different types of organisms. I believe there are now some 32 types of pneumococci and I do not know how many types of streptococci and influenza bacilli. To get sputum from a child is by no means easy, and if one does obtain it one cannot be scientifically sure that the organisms found are those which caused the disease. To attempt to stick a swab into the larynx of a desperately sick child is not an ideal therapeutic procedure. We tried to get sputum from this little boy but the effort was so exhausting to him that we did not repeat the attempt, and the report from the swab was "no pneumococci found," although the case was a typical out and out clinical lobar pneumonia. Not only should one know the organisms in the patient but one should know the type of disease formerly present in the donor. Hence, really to get at the matter scientifically requires a very elaborate procedure. However, I have used convalescent serum trying to be as scientific as possible, and still must confess that it seems to be a more or less hit or miss procedure. There are some cases in which the serum may have been of real value. I have seen the temperature drop quite suddenly following injections. But we have all seen that happen without serum. In one patient with a temperature over 107° F. and almost moribund, following a second dose of 100 cc. of convalescent serum intravenously, there was the severest chill I have ever seen, during which the patient almost died. The temperature then dropped to subnormal, then rose in six hours to 104° F., then dropped to normal and remained there. Was this recovery due to the serum? Was this collapse due to poor technic? Ordinarily one should allow an hour for the procedure. Was it an allergic reaction and just an added aggravation during a spontaneous crisis? Your guess is as good as mine. This is

the only case where I have seen any severe reaction following the use of convalescent serum.

In brief, then, I am willing to confess that I am at a loss as yet whether or not to recommend convalescent serum. It may be of value in specific cases. It may supplement blood transfusion. If one by good fortune gets a serum which contains the proper antibodies it may be life-saving. As a general routine, however, without expert supervision for the treatment of the average case seen in ordinary practice and with our present knowledge, I believe that equally good or even better results are obtained by blood transfusion.

## CLINIC OF DR. HUGO R. RONY

### NORTHWESTERN UNIVERSITY MEDICAL SCHOOL

---

#### NONOPERATIVE (GONADOTROPIC) TREATMENT OF CRYPTORCHISM

SINCE 1930 when Schapiro<sup>1</sup> first reported successful treatment of human cryptorchism by injections of the gonadotropic principle of pregnancy urine, this type of treatment has been applied by a number of clinicians with variable results. As is frequently the case with new therapeutic procedures, the first enthusiastic reports were soon followed by expressions of skepticism and caution. In the meantime sufficient experimental and clinical material was accumulated to allow for a clearer appreciation of the possibilities and limitations of this treatment. To this end it is necessary to keep in mind some pertinent physiological and pathological data.

Normally the testicles descend from the abdominal cavity through the inguinal canal into the scrotum during the seventh to eighth month of intra-uterine life; at birth both testicles are found in the scrotum. Nothing definite was known about the physiological mechanism of the descent of the testicles until 1932 when Engle<sup>2</sup> suggested that maternal gonadotropic hormones play an important part in it. This contention is supported by the following observations: (1) The human is the only organism known in which testicular descent occurs before birth, and the human female is also the only one having gonadotropic hormones in blood circulation throughout the period of gestation. (2) A noticeable increase in the number of the interstitial cells of the testicle of the human fetus occurs one to two months before term; a similar change may be experimentally produced in immature monkeys by injections of the gonadotropic hormone of pregnancy urine. (3) In imma-

ture monkeys and rats injections of the pregnancy urine gonadotropic hormone cause premature descent of the testicles. (4) An analogous phenomenon indicating effects of maternal female sex hormone is occasionally observed in newborn girls showing swelling of the major labia or breasts. These and similar other observations may be considered as sufficient evidence to indicate that in the normal fetal descent of the testicles gonadotropic hormones of the mother are instrumental.

If the testicle fails to descend before birth, it usually remains undescended until the beginning of puberty. The descent may be arrested at any point, in some cases in the abdominal cavity, more often in the inguinal canal. The arrest may be bilateral, both testicles being arrested at the same point or at different points. In the majority of the cases unilateral arrest is observed, the other testicle being in normal position. Drake<sup>3</sup> observed 11 cases of cryptorchism among 260 boys nine to nineteen years of age—a frequency of 42 per thousand. It has been known for many years that spontaneous descent of undescended testicles may occur at puberty, but the frequency of this phenomenon was not realized until recently. It appears that spontaneous pubertal descent occurs in the majority of cases of cryptorchism; it occurred in 9 out of 11 of Drake's cases. This is confirmed by the fact that cryptorchism is not nearly as frequent in the adult population: extensive statistics obtained on army recruits in different countries indicate an incidence of 2 to 5 per thousand.

While the normal fetal descent of the testicle occurs under the influence of maternal gonadotropic hormones, late spontaneous descent in puberty is thought to be brought on by the gonadotropic hormone of the hypophysis of the individual.

Histologically the undescended testicle, prepubertal or postpubertal, shows a picture similar to that of a normal prepubertal scrotal testicle. In other words, the undescended testicle fails to supply at puberty its seminiferous tubules with normal germinal epithelium, and remains aspermic and sterile. It has been shown conclusively by Moore<sup>4</sup> that scrotal position is necessary for the normal development of the germinal

epithelium because of the lower temperature it insures. If a mature scrotal testicle with the spermatic cord intact is placed in the abdominal cavity, soon most of the germinal epithelium degenerates and disappears; replacement of such a testicle into the scrotum is followed by regeneration of the germinal epithelium and spermatogenesis. However, the abdominal testicle may produce male sex hormone in apparently undiminished amounts, as demonstrated by Moore in experiments on guinea-pigs.

**Classification.**—*Group A.*—In a number of cases of human cryptorchism examination of the patient fails to disclose any additional pathology of importance. There are no signs of disturbance of the endocrine system; growth, sexual and mental development are normal. Puberty appears in due time with all secondary sex characteristics and sexual potency. The majority of unilateral cryptorchism cases and a few of the bilateral ones belong to this category. Failure to descend may be due to causes of local anatomical nature, such as developmental error, or adhesions due to fetal peritonitis; in these cases spontaneous late descent at puberty will not occur. In other cases descent is arrested before birth because of deficiency in maternal gonadotropic hormones; late spontaneous descent frequently sets in at puberty under the stimulation of the normally functioning anterior pituitary. Clinical differentiation between these two subgroups can, as a rule, not be made before puberty.

*Group B.*—In most cases of bilateral cryptorchism clinical examination reveals more or less marked signs of hypogonadism. The scrotum is undeveloped, the penis is infantile, the prostate and seminal vesicles are hypoplastic. The patient is more or less obese with a girdle type of fat distribution. Puberty is delayed and imperfect, or entirely missed. Late spontaneous descent rarely occurs. The undescended testicle remains not only sterile but also deficient in the production of the male sex hormone on which the development of the secondary sex characters depends.

The hypogonadism is usually secondary, being due to

deficient gonadotropic activity of the hypophysis; it is frequently accompanied by signs of deficiency of other functions of the hypophysis, such as stunted growth, diabetes insipidus, subnormal mentality, delayed dentition, etc. The question arises whether the fetal arrest of testicular descent is also due to the pituitary deficiency. There is no evidence that the hypophysis of the fetus has any active rôle in the physiological mechanism of testicular descent. Furthermore, a number of cases of most severe hypopituitarism are born with scrotal testicles, even though the further development of these testicles will be seriously impaired. Accordingly, it must be assumed that the fetal arrest of descent is independent from the pituitary failure of the patient in cases of hypogonad cryptorchism. On the other hand, the absence of late spontaneous descent is obviously a consequence of the patient's deficient pituitary gonadotropic hormone production.

In some cases cryptorchism is associated with primary hypogonadism: there is congenital idiopathic hypoplasia of the testicles, or atrophy following orchitis as a complication of mumps, etc. The gonadotropic activity of the anterior pituitary is intact in these cases. Clinically they usually present the picture of eunuchoidism with the typical body proportions and delayed union of epiphysial junctions. Differentiation between primary and secondary hypogonadism, associated with cryptorchism, may be difficult in some cases.

**Specificity of Gonadotropic Therapy.**—Injections of gonadotropic hormone preparations in cryptorchism have been followed in many cases by descent of one or both testicles. Some doubt has been expressed as to the specificity of this effect in view of the fact that spontaneous descent frequently occurs; the result might be merely coincidental. However, a number of observations are available which would be difficult to explain on the basis of coincidence: (1) In many cases gonadotropic therapy was followed by descent of the testicles in four- to six-year-old boys, and in some cases in eighteen- to twenty-seven-year-old men, *i. e.*, at ages when spontaneous descent very rarely occurs. (2) Results were frequently ob-

served within two weeks of treatment. (3) In some cases descent occurred during treatment but the testicle again retracted into the inguinal canal or abdominal cavity shortly after the injections were discontinued. A second course of injections brought the testicle down again. (4) Cases were observed that were previously operated on, the testicle being placed in the scrotum; subsequent retraction occurred; gonadotropic treatment was followed by descent. In view of such observations it is safe to say that descent of cryptorchid testicles may be the direct result of gonadotropic therapy.

**Indications for Gonadotropic Therapy.**—Obviously, gonadotropic treatment is indicated in all cases belonging to Group B, although favorable results are not always obtained. Why treatment fails in some patients of this group is difficult to say. Possibly, in some cases, local anatomical causes exist in addition to the deficiency of the anterior pituitary. In primary hypogonadism (eunuchoidism) the lesion of the cryptorchid testicle may be so severe as to obviate response to the strongest gonadotropic stimulation. In other cases the intensity or duration of the treatment might have been insufficient.

In some patients belonging to Group A gonadotropic treatment is doomed to failure because of the presence of anatomical obstacle. In other cases of this group treatment is superfluous as descent will spontaneously occur at puberty. Only in a relatively small number of cases is hormonal treatment both necessary and successful. Unfortunately, the nature of the case is not, as a rule, recognizable before puberty. Accordingly, correct indication for hormone therapy can hardly be made when the patient is seen before puberty. If cryptorchism persists in the presence of more or less marked pubertal changes, a trial with hormone therapy is indicated. Failure of this therapy may be considered as evidence of anatomical obstruction and indication for surgical interference.

Postoperative hormonal treatment—following orchiopexy—has been advocated to insure against possible retraction of the testicle (Spence and Scowen<sup>7</sup>).

At what age should treatment be started? Cryptorchism is an abnormal condition at any age and it might seem logical to attempt to correct it as early as possible. In fact, several clinicians expressed this opinion and a number of four- to ten-year-old successfully treated children are on record. It is not quite clear to me what is to be gained by producing testicular descent artificially at this early age unless some special indication, such as local pain, or hernia exists.

For cases of Group B with marked genital dystrophy (undeveloped scrotum and penis) advisability of early treatment may be a matter of opinion: the testicle in these patients is not only undescended but hypoplastic as well; chances for spontaneous late correction are slight. Yet, even in these cases treatment at the normal beginning of puberty—eleven to thirteen years—rather than earlier appears to be the logical procedure.

For Group A early treatment is hardly justified. As I mentioned before, a normal prepubertal undescended testicle does not differ histologically and functionally from a normal prepubertal scrotal testicle, and scrotal position becomes of great importance for the structure and function of the testicle only with the onset of puberty. In patients of Group A, general development, including sexual development proceeds normally whether the testicle is in the scrotum or in the abdomen. Furthermore, in many instances spontaneous descent occurs at puberty. Accordingly, there is no reason why one should not wait with treatment of patients of this group until puberty is well established, at fourteen or fifteen. It is probably not advisable to wait much longer. I have found no report in the literature of successful treatment of patients older than eighteen, belonging to this group.

**Some Technical Details of Hormone Therapy.**—Most authors used preparations of the pregnancy urine gonadotropic hormone (prolan, anterior pituitary-like substance). Others used extracts made from the anterior lobe of the hypophysis. There is no evidence that either one is superior. In the presence of signs of hypothyroidism desiccated thyroid gland may be given simultaneously.

Injections of the pregnancy urine gonadotropic hormone are given daily or every other day subcutaneously or intramuscularly, 100 to 300 rat units each time. The duration of treatment and the total amount of the hormone administered varies greatly. In some cases a few hundred units given within two weeks prove sufficient. In other cases (Group B) treatment was continued for over a year with a total amount of 20,000 or more units injected. It is probably safe to say that if the injection of 10,000 units fails to produce any change, further treatment at that time is not likely to succeed. In such cases it may be advisable to undertake a second course of injections starting a few months later, as suggested by Spence and Scowen.<sup>5</sup> They quote the work of Sellye *et al.*,<sup>6</sup> who have shown that after prolonged administration of gonadotropic hormone virgin female rats become temporarily insensitive to the hormone. Repetition of treatment is also indicated when the testicle which has descended after a course of injections, later retracts into its previous position. As a rule, treatment is discontinued as soon as the testicle reaches the bottom of the scrotum, although in cases associated with sexual infantilism it may be necessary to continue hormonal treatment over a longer period.

**By-effects of Hormone Therapy.**—In some cases mild to moderate pain is complained of in the groin of the affected side during treatment. This does not necessitate interruption of treatment as the pain soon subsides.

After the testicle has descended it is usually smaller than normal but soon reaches normal proportions. Enlargement beyond the normal for the patient's age is not produced even when treatment is continued with large doses. The same is true for the scrotum and penis. Precocious secondary sex characteristics—such as pubic hair, mutation of voice, etc.—in children treated before puberty were not observed, except by Dorff<sup>7</sup> who gave very large amounts of the hormone (as much as 46,000 units). Neither is enlargement of the prostate or of the breasts of the patients reported, although Geschickter *et al.*<sup>8</sup> reported such effects in monkeys treated with large amounts of pregnancy urine hormone.

The question whether the testicle, which has descended into the scrotum in response to hormonal therapy, becomes fertile cannot be answered directly at this time. Some indirect evidence is available. Thus it is known that bilateral undescended testicles brought down into the scrotum by surgical orchiopexy may become fertile (MacCollum<sup>9</sup>). Brosius and Schaffer<sup>10</sup> reported a case of bilateral testicular atrophy with complete aspermia following orchitis as a complication of mumps, in which gonadotropic hormone therapy repeatedly produced extensive spermatogenesis.

Huberman<sup>11</sup> and Dorff<sup>7</sup> noticed marked improvement of mental development and enuresis nocturna in some of their cases treated for cryptorchism. Accelerated growth is sometimes observed. It appears that when the gonads mature under gonadotropic treatment, they exert a stimulating influence on growth, probably by way of the anterior lobe growth-promoting apparatus.<sup>12</sup>

Gonadotropic treatment has no effect on the obesity associated with genital dystrophy. The obesity and the type of fat distribution usually persist even after complete correction of cryptorchism and sexual underdevelopment. Neither is there any definite change in basal metabolism.

A unique observation of enuresis, polydipsia and glycosuria appearing during gonadotropic treatment for cryptorchism in a thirty-month-old child is reported by Koplin<sup>13</sup>; all symptoms disappeared after three weeks following the termination of treatment. This may be considered as another reason against gonadotropic therapy at early age.

#### PRESENTATION OF CASES

**Case I.**—This boy is now thirteen years old. He is normally developed. Both testicles are in the scrotum; their size is normal for his age. He was a normal boy when I saw him first about a year ago, except for a unilateral cryptorchism. The left half of the scrotum was empty, as was the left inguinal canal. We gave him injections of 200 units antuitrin-S three times a week. After the sixth injection the left testicle de-

scended into the scrotum and soon reached the size of the right testicle. I have no doubt that the gonadotropic therapy was instrumental in the descent of this testicle, although it is quite possible that descent would have occurred by this time, or later, without any therapy. We now believe that such cases do not need treatment before they reach their fourteenth or fifteenth year.

**Case II.**—This boy is twelve and one-half years old. He has bilateral cryptorchism; no trace of the testicles can be found on physical examination. Otherwise he is normally developed in every way. We have started with gonadotropic therapy five months ago, giving him daily injections of 100 units antuitrin-S. On the tenth day I found the right testicle in the scrotum, the left testicle in the inguinal canal. After waiting for four weeks without noticing further change, we gave him again daily injections of the same substance and amount. Two weeks later both testicles were in the scrotum. He has received altogether 2400 units of the hormone. Now he returns with both testicles retracted into the abdominal cavity. Another course of injections would probably bring these testicles down again, and with continued treatment they might stay in the scrotum permanently. But we might as well wait for a year or two without treating this patient. In the meantime the testicles may spontaneously descend. If this will not occur, we will then try another course of hormone injections. Small amounts of the hormone will probably suffice at that time to insure permanent result.

**Case III.**—Two years ago this patient presented a typical picture of adiposogenital dystrophy. He was then thirteen years old, his height was 63 inches, his weight 123 pounds. The scrotum and penis were markedly underdeveloped; a tiny structure, of the size of a small pea, was found in the left half of the scrotum; the right half of the scrotum and the right inguinal canal were empty. He had an average intelligence. His basal metabolism was  $-26$  per cent. His bone development was two years advanced as indicated by x-ray pictures of his hands and

lower arms, a finding which is not infrequently associated with genital underdevelopment.

Gonadotropic treatment was started in March, 1934. He received daily injections of antuitrin-S, 100 units each time for thirty days. At the end of this period I found both testicles in the scrotum; they were not larger than small peas. After four weeks we gave another course of 20 injections in the same way as before. After another month we tried an anterior pituitary gonad-stimulating preparation, prephysin, which was given in daily injections, 25 units each, for six weeks. Altogether he received 11,200 units of antuitrin-S and 1050 units of prephysin. There was no further change, and we decided to wait for a while. About a half year later, in May, 1935, the right testicle was much larger, of the size of a cherry, the left remained as small as it was. The penis and scrotum have shown some development, and there was some pubic hair. It appeared that he was entering puberty and we again decided against interference. As you can see from his present state, this was justified. The appearance of his external genital organs is now almost normal: both testicles in scrotum, the right testicle is of normal size and consistency, the left is somewhat smaller and softer. The penis is of normal size, and there is pubic hair present. His voice is in mutation. His height is now 68 inches, weight 131 pounds, basal metabolic rate —20 per cent.

We believe that the prompt descent of the right testicle, after one month's treatment, was due to the gonadotropic therapy. Whether this therapy was also instrumental in bringing about his puberty is open to question. We have in our care another boy, now eighteen years old who five years ago was a typical case of adiposogenital dystrophy and who at fifteen entered puberty and eventually showed perfect genital development, without any treatment whatsoever. Undoubtedly, in some cases of adiposogenital dystrophy spontaneous adjustment occurs at puberty.

As you see, the patient is still obese, and I may add that his type of fat distribution, thought to be characteristic for adiposo-

genital dystrophy, is quite the same as it was two years ago when he was sexually infantile. This indicates that the hypogonadism is not the cause of the obesity with which it is so frequently associated.

**Case IV.**—This boy was first seen fourteen months ago when he was fourteen years old. He had bilateral cryptorchism. The small and empty scrotum was in peculiar contrast to the large penis. There was no pubic hair. A slight but definite gynecomastia was present. He was undersized, his height being 57 inches. He was obese, weighing 118 pounds. There was marked delay in dentition. His intelligence was definitely subnormal. Basal metabolic rate was —6 per cent. I classified the case as a cretinoid.

Starting in February, 1935, he received 5600 units of antuitrin-S and 250 units of prephysin within three months. At the end of this period a cherry-size testicle was found in the right side of the scrotum; the left testicle was still missing. Pubic hair appeared. In September, 1935, we gave another course of injections, 1400 units of antuitrin-S in three weeks. There was no immediate change, but a half year later, now, the right testicle is of normal size, in the scrotum, and the left testicle about half as large, in the inguinal canal. His height is 61 inches, a growth of 4 inches in fourteen months, which is rather remarkable in view of his slow growth before. His weight is 122 pounds. The gynecomastia is hardly noticeable now. There is no apparent change in his mental capacity.

**Case V.**—This young man is twenty-one years old. He was admitted to the clinic two years ago. He complained of severe nosebleeds and extensive subcutaneous hemorrhages which were found to be due to thrombocytopenic purpura. In addition, he had a unilateral cryptorchism. The right testicle, penis, prostate, pubic hair, and sexual manifestations were normal; the left testicle, of the size of a cherry, was found in the middle of the inguinal canal.

Four thousand units of antuitrin-S were administered within two months, without noticeable effect. Half a year later 11,000

units of antuitrin-S were injected within four months. As you see, the cryptorchism persists. We may conclude that in this case an anatomical obstruction exists which cannot be eliminated except by surgical intervention.

**Case VI.**—You will recognize this case by inspection as that of eunuchoidism. He is thirty-three years old. He is tall and obese with a female type of fat distribution. His extremities are relatively long, the trunk relatively short. There is very little pubic hair and no body hair; he shaves once in two weeks. The penis and scrotum are infantile, the prostate is hardly palpable. There is a scar in the right inguinal region; he was operated on that side for cryptorchism at thirteen, unsuccessfully; there is no trace of the right testicle. In the left inguinal canal a small firm structure, of the size of a navy bean is palpable. He complains bitterly of his greatly impaired sexual ability.

We have given this patient in the past two years 27,000 units of antuitrin-S and 1000 units of prephysin. He noticed occasional slight pain in the left groin, faster growth of facial hair, and more frequent sexual manifestations. But the testicle is as small as it was before, and remains in the inguinal canal. We advise orchiopexy to be followed immediately by gonadotropic therapy. This may help if viable testicular tissue is still present in the structure palpable in the inguinal canal.

## CLINIC OF DR. AARON ARKIN

COOK COUNTY AND MT. SINAI HOSPITALS

---

### ESSENTIAL HYPERTENSION AND CARDIOVASCULAR- RENAL DISEASE

THIS clinic will be devoted to a discussion of essential hypertension and cardiovascular-renal disease.

Essential hypertension or primary arterial hypertonia is a cerebral functional disorder affecting the vasomotor apparatus, and is characterized by a hypertonus of the arterial system. This hypertonus leads to a progressive increase in the systolic and diastolic blood pressure, followed by cardiac hypertrophy and cerebral, renal, retinal and other vascular changes. The disease often continues for years without producing any subjective symptoms and is frequently diagnosed at a late stage when cerebral, cardiac, renal, or ocular symptoms appear. The diagnosis in the early or functional stage can be made by finding an increased tonicity of the arteries with a variable hypertension, spastic retinal arteries with tortuosity of the venules, and beginning hypertrophy of the left ventricle. The diagnosis in the advanced or organic stage is based upon the presence of a more or less fixed high systolic and diastolic blood pressure, rigid arteries, marked cardiac enlargement, hypertensive retinitis, and eventually signs and symptoms of cerebral, cardiac, or renal disease.

In making a diagnosis of essential hypertension it is naturally assumed that other causes of hypertension such as: (1) glomerular nephritis, (2) polycystic kidneys, (3) urinary obstruction, (4) increased intracranial tension, (5) eclampsia, (6) adrenal tumors, (7) pituitary basophilic adenoma, (8) lead poisoning, (9) periarteritis nodosa of the kidneys, (10)

polycythemia, and (11) coarctation of the aorta, are excluded whenever possible.

In exceptional cases the disease may run a more acute rapidly fatal course. This is due to extensive renal arteriolar changes which lead to extremely high blood pressure readings and death from renal decompensation, acute cardiac failure, or cerebral hemorrhage. On the other hand, the hypertension in the chronic cases frequently decreases with myocardial damage and many patients in the late stage present little or no hypertension. But these persons have a large heart, retinal changes, a relatively low pulse pressure, and evidence of cardiac failure usually without valvular heart disease. A rheumatic or luetic heart disease may be aggravated by an arterial hypertonia.

A better understanding of the nature of essential hypertension will benefit the many sufferers from this ailment. Fewer costly and often harmful drugs will be used in this disease, for which there is no specific cure. We shall see that a suitable restful régime of reduced mental and physical strain, rest periods and increased hours of sleep, and reassurance by the physician constitute the treatment of primary arterial hypertension. The drugs of chief value are sedatives, and those which lower the blood pressure in vascular crises. Marked lowering of pressure in advanced hypertension is usually harmful rather than beneficial.

#### THE NORMAL BLOOD PRESSURE

The normal blood pressure in adults, of 120 to 150 systolic and 80 to 95 diastolic, is maintained by the tonus of the arterioles and the action of the heart. It is subject to considerable psychic influence. The arteriolar tonus is regulated by the action of the vasodilator and vasoconstrictor impulses from the central nervous system. The diastolic pressure is a measure of the peripheral resistance within the vascular system, the systolic pressure measures the total contractile force of the left ventricle. Unfortunately we have no means of measuring the systolic and diastolic pressure in the pulmonary artery of the right heart. The blood pressure in the pulmonary

artery is normally about one third that of the aorta, hence the right ventricle is normally thinner than the left and the right coronary artery usually presents less atherosclerosis than the left.

The pulse pressure, or difference between the systolic and diastolic pressure, measures that portion of the ventricular force which is available for propelling the blood through the vascular tree. It is normally about one half of the diastolic and one third of the systolic pressure. This is the well-known 1-2-3 relationship which is found in normal persons.

### THE NATURE OF ESSENTIAL HYPERTENSION

The etiology of primary arterial hypertension has not yet been entirely solved by experimental, clinical, or anatomical studies. Four endocrine glands have frequently been blamed, the adrenal, pituitary, thyroid and sex glands. Many workers have been concerned with the study of the blood for substances acting on the blood vessels. A specific pressor substance has not been found in the blood of hypertensives. Hypertonus of the walls of the circulatory apparatus occurs in two forms. There is an arterial form, and a generalized form which involves the entire circulatory system. We wish to discuss the first type, primary arterial hypertonia or essential hypertension. The second type is the toxicogenic or renal type.

Hypertension is a symptom of the hypertonus of the arteries of the systemic circulation. Without an increased tonicity or hypertonus of the arterial and arteriolar walls there can be no high blood pressure in essential hypertension. But hypertonus can occur without high blood pressure when only a part of the peripheral arterial system is affected, or the heart has become decompensated. The hypertonus, especially in the early stage, varies in its intensity and distribution. When a large vascular area such as the splanchnic is involved the blood pressure will rise; when a small area such as an extremity or a single organ is affected there may be little or no rise of blood pressure. When the hypertonus becomes persistent and leads to a hypertension the heart, blood vessels, brain, kidneys, eyes

and other organs suffer organic changes. There is an increased susceptibility of the arterial walls to spasms, producing harmful angiospastic crises with further circulatory derangement and dangerous rises in blood pressure. Such crises, according to Pal, may be regional or generalized.

Essential hypertension often commences in young adults with an hereditary predisposition. The most important factor is the psychic influence. Most of the patients are neurotic and temperamental. The most frequent subjective symptoms are headaches, vertigo, and irritability. The individuals are easily upset, often suffer from migraine headaches. Pain in the back of the neck or occipital region is common. Some complain of palpitation of the heart, especially when lying on the left side. Blood pressure readings will show marked variations in the systolic and diastolic pressure. Excitement or aggravation frequently causes rises of 20 mm. or more, rest or sleep a return to normal. A systolic pressure above 150 mm. with a diastolic above 95 we consider to be an hypertension. In severe cases of malignant nephrosclerosis we often see systolic pressures above 250 and diastolic above 160 mm.

In essential hypertension there is an increased peripheral resistance which must be overcome to maintain an adequate circulation. The resistance manifests itself by a rise in the diastolic pressure. This leads to hypertrophy of the left ventricle. As long as the heart can increase its force and maintain an adequate pulse pressure the individual may suffer few or no symptoms. When the heart begins to fail there is a reduction in the systolic pressure, which means the pulse pressure is lowered. Since the diastolic pressure can fall very little or not at all, the decrease in the systolic pressure is at the expense of the pulse pressure and must end in circulatory failure. As long as the hypertrophied heart can maintain a pulse pressure approximately one half as great as the elevated diastolic pressure a fairly adequate circulation is maintained. This explains why some hypertensives can carry on for ten or twenty years or longer with diastolic pressures of 110 to 130 and systolic pressures of 180 to 200.

## THE HEART IN ESSENTIAL HYPERTENSION

In essential hypertension there is a progressive increase in the tonus of the arteries and arterioles which produces a swelling of the walls with constriction of the lumen. At first this process is reversible, but later the walls become thickened with permanent narrowing. The increase in the systolic and diastolic blood pressure leads to a remarkable adaptation of the heart and circulation. In spite of high pulse pressures the heart rate, stroke volume, minute volume output of the heart, and the blood volume remain essentially normal.

The heart muscle undergoes a compensatory hypertrophy, perhaps also an increase in tonus of the musculature. The hypertrophy is at first concentric with marked thickening and some shortening of the muscle fibers, later eccentric with elongation of the fibers. The cardiac hypertrophy, which is so essential in overcoming the increased peripheral resistance, unfortunately also leads to eventual cardiac decompensation unless the patient succumbs to a cerebral insult or renal failure. The heart often does its greatly increased work for ten, twenty or more years before the symptoms of failure appear. During all this time the person may not be aware of any primary arterial hypertension unless the blood pressure is taken or the eyes are examined.

I have for over a decade called attention in my clinics to the fact that essential hypertension is one of the chief causes of cardiac failure, and that 65 per cent of hypertensives die from heart disease. Today one fourth of all deaths in people above the age of fifty years are due to hypertensive heart disease. I have also emphasized the fact that the marked myocardial hypertrophy leads to insufficiency of the coronary blood supply. The muscle cells often increase to two or three times their former size and suffer from a relative anoxemia which leads to their degeneration and fibrosis. The anoxemia explains the cardiac failure in many hypertensives who reveal little or no coronary sclerosis at necropsy. When we add to the anoxemia of marked hypertrophy the further factor of coronary arteriolar spasm with marked reduction of the blood flow, it is not difficult

to explain myocardial failure with little or no gross coronary disease. The many hypertensives who survive for years and are past the fifth decade of life will of course present different grades of coronary sclerosis. Coronary thrombosis or embolism may cause myocardial infarction. The heart may reach a tremendous size, and often weighs 600 to 800 Gm.

**Case I.**—Mr. E. A. G., fifty-five years of age, states that he was well until six months ago. At that time he developed pain in the heart region with radiation to the left arm and neck. The pain was induced by physical exertion, and disappeared with rest. Now the pain is more severe, lasting ten to twenty minutes and occurs several times a day. There is a marked nocturnal dyspnea and insomnia. The patient cannot lie on his left side on account of palpitation of the heart.

The patient was told five years ago that he had a high blood pressure and was refused life insurance. Since that time he had been able to attend to his duties as a dairy inspector.

There is a moderate cyanosis and dyspnea. The pupils react normally to light, the patellar reflexes are normal. The fundi reveal a hypertensive retinitis, with narrow arteries, exudates and small hemorrhages. The pulse rate is 96, with occasional extrasystoles. The radial arteries are very firm, and difficultly compressible. The blood pressure is 188 systolic and 128 diastolic. The heart is of the aortic type with a transverse diameter of 7 inches (orthodiagram). The aortic second sound is loud and ringing, there are no murmurs. The liver is palpable 1 inch below the costal margin. There is slight edema of the legs. There are moist râles at both lung bases. Wassermann and Kahn tests are negative. The urine contains a trace of albumin and a few casts. The blood non-protein nitrogen is 45 mg.

The patient improved for a time with bed rest, aminophyllin, and digitalis. The anginal pains disappeared with more marked evidence of cardiac failure. The blood pressure dropped to 148 systolic and 110 diastolic.

The diagnosis was essential hypertension, with marked

cardiac hypertrophy and dilatation, angina pectoris, and cardiac decompensation. The patient died suddenly of cardiac failure. The necropsy revealed primary contracted kidneys of hypertension, marked hypertrophy and dilatation of the heart which weighed 750 Gm., and practically no sclerosis of the coronary arteries. The heart muscle presented a marked diffuse fibrosis. There was no valvular disease.

This case illustrates one of the most frequent causes of cardiac failure, with attacks of angina pectoris. The cause of death was the severe anoxemia of the greatly hypertrophied heart with practically no coronary disease. The patient knew of his hypertension for five years, but probably had it a much longer time.

#### THE BRAIN IN ESSENTIAL HYPERTENSION

One fourth of all persons with essential hypertension die from cerebral changes which are chiefly hemorrhage or encephalomalacia. Here as in the myocardium degeneration is often found in the presence of normal arteries, again indicating that blood vessel spasms produce the lesions. Such spasms or vascular crises will lead to necrosis and softening if the blood supply is cut off for more than a minute or two. That cerebral vascular spasms are frequent in essential hypertension is indicated by the many transient cerebral symptoms. I have often seen paresthesias, motor aphasia, monoplegia, hemiplegia, twitchings in single muscle groups, epileptiform seizures, severe migraine headache, vertigo and sudden blindness appear and disappear in these patients. We shall see that some of these symptoms may lead to the mistaken diagnosis of brain tumor or hemorrhage. In some of these patients there is an increased pressure of the cerebrospinal fluid, with some relief from spinal puncture. These cerebral manifestations, sometimes called hypertensive encephalopathy, may be premonitory symptoms of more serious brain involvement.

Cerebral hemorrhage and thrombosis are the most frequent cause of death in the cerebral type of essential hypertension. The favorite site of hemorrhage is the region of the basal

ganglia. Here the blood vessels have large perivascular spaces, and the surrounding brain tissue has a poor blood supply. Small areas of softening combined with a sudden increase of blood pressure will cause rupture with hemorrhage. Often the vessels are sclerosed. The most common cause of cerebral hemorrhage is hypertension. A sudden severe headache or vomiting at the onset is strongly in favor of the diagnosis of hemorrhage. Unconsciousness or coma develops in 70 per cent of the hospital cases. A bloody spinal fluid, stiffness of the neck, a high leukocyte count, systolic blood pressures of 200 or above, loss of pupil reflexes, dilatation of one pupil, and positive Babinski sign are the usual findings in cases of cerebral hemorrhage.

**Case II.**—This case is very instructive because a diagnosis of brain tumor was made by two neurologists who advised operation.

The patient, a white male, fifty-three years old, was first seen in August, 1928. At that time he stated that he was refused life insurance by two companies on account of his blood pressure and heart condition. Since 1920, he had occasional dizzy spells lasting one-half to one hour. He is a very nervous, easily excitable person, eats rapidly and irregularly and is unable to relax. The blood pressure in August, 1928, was 160 systolic and 105 diastolic. The heart was slightly enlarged with rounding of the left ventricle. There were no murmurs. The aortic second sound was accentuated. All reflexes were normal. The fundi revealed spasm of the arteries with tortuous veins around the macula. The Wassermann was negative, urine normal.

The patient was advised of the importance of keeping serene, rest periods, and mental relaxation. He felt well for two years, the blood pressure varying between 150 and 190 systolic pressure, and 95 and 110 diastolic. In April, 1931, the patient had severe occipital headaches, pain in the back of the neck, left shoulder and left arm. There were two attacks of cardiac pain lasting five to ten minutes. The blood pres-

sure had risen to 200 systolic and 130 diastolic. With sedatives, metaphyllin and occasional use of erythrol tetranitrate the patient felt quite well for four years. The blood pressure was around 170 systolic and 120 diastolic. The patient received streptococcus vaccine from another physician for his arthritic and neuralgic pains with some benefit.

In January, 1936, the patient went to the bathroom and developed a sudden blindness. He got into bed and stayed there several days. After three days' rest the blood pressure was 200 systolic and 130 diastolic. He developed severe frontal and occipital headaches. Examination revealed no evidence of sinus infection. On February 13th, the patient noticed a numbness of the right side of the body and weakness of the right hand. At times he dropped things. On February 17th, he had a severe headache in the left temporal region with loss of speech. While talking on the telephone he suddenly found himself unable to express his thoughts, though fully aware of his surroundings. For a week there were intermittent attacks of the motor aphasia. At times there was a twitching of the right arm and leg, with weakness. Two neurologists were consulted who diagnosed a brain tumor in the left temporal region and advised operation. There was no choked disk! The writer held to his diagnosis of hypertensive encephalopathy with cerebral-vascular spasms and intermittent motor aphasia and paresis. A third consultant agreed. The patient's symptoms disappeared the next day with rest in bed and the administration of theominal. From February to July, 1936, the patient has felt well, and there have been no recurrences of the motor aphasia or paresis. The patient is resting much of the time, and usually feels better in warm weather. The blood pressure is now 170/120.

The above case is an excellent example of the cerebral form of essential hypertension, most likely due to cerebral vascular crises with spasms of the cerebral vessels, perhaps even minute hemorrhages, or areas of softening. Nevertheless the patient's symptoms all disappeared. We may add here that patients with essential hypertension are poor surgical risks especially

for brain surgery, and that one should be very hesitant in making a diagnosis of brain tumor in a hypertensive, with hypertensive retinitis but no choked disk. Even the presence of choked disk may be due to the cerebral edema of hypertension.

**Case III.**—This man, forty-five years old, was referred for examination on January 24, 1935. His mother, seventy-two years old, has had hypertension and heart disease for twenty years. The father has diabetes and obesity. Seven years ago the patient obtained life insurance. Four years ago he was refused because of obesity and hypertension. One year ago he developed a left facial paralysis which disappeared after six weeks. In September, 1934, the patient had several attacks of severe abdominal pain diagnosed as renal colic; they were accompanied by slight hematuria. At the same time there were severe occipital headaches, and twitchings of the left arm and leg for one week. The patient's vision became poorer and his glasses were changed.

The examination on January 24, 1935, revealed a moderate obesity, pendulous abdomen, and pectoral alopecia. The pupils reacted normally to light. Fundus examination revealed a marked neuroretinitis. The blood pressure was 230 systolic and 150 diastolic. The heart was of the aortic type with a transverse diameter of 6 inches. There was a very loud ringing aortic second sound, no murmurs. The liver and spleen were not palpable. There was no edema. The left arm and leg became spastic at times with exaggerated reflexes. The Wassermann was negative. The blood sugar and nonprotein nitrogen were normal.

With rest, phenobarbital, and erythrol tetranitrate the patient improved. The twitchings disappeared, as did the headaches. The patient returned to work against my advice. The twitchings of the arm and leg returned, and the blood pressure rose again from 190/130 to 240/160. The patient developed an upper respiratory infection with fever and the blood pressure dropped to 200/140. On April 25th, the patient complained of considerable dyspnea, and some cardiac pain

on exertion. The blood pressure was 240/160. He was ordered to bed and improved. Two months later the patient, suspecting that his condition might be serious, decided to visit his mother in the East. After a long automobile trip he complained of intense headache and died of a cerebral hemorrhage. The clinical diagnosis of essential hypertension, with marked cardiac enlargement, arteriolosclerotic primary contracted kidney, and cerebral hemorrhage was confirmed at necropsy.

### THE KIDNEY IN ESSENTIAL HYPERTENSION

The third organ affected in primary arterial hypertension is the kidney. As Pal stated about thirty years ago, the kidney changes are not the cause of the hypertension. In the early stage there are no organic kidney changes. As the disease progresses arteriolar hypertrophy and fibrosis, or arteriolosclerosis, develop and reduce the blood supply to these vital organs. We have then the primary contracted, red granular kidney of essential hypertension. This process may be very slow extending over years. In about 10 per cent of cases the renal changes are rapid and lead to decompensation with uremia. This form, seen most often in young adults, especially negroes, is called malignant nephrosclerosis or malignant hypertension. These patients have a generalized more severe hypertonus of the entire vascular system, with angiospastic crises. The highest blood pressures which we find are usually in this form. Systolic pressures of 250 or more and diastolic pressures above 160 are not uncommon. This is the pale hypertension of Volhard, which may be called toxigenic or renal hypertension in contrast to the primary arterial.

The renal or toxigenic hypertension is more generalized and more rapid in its development. It affects the heart muscle, arteries, arterioles, and venous system. The entire cross section of the vascular apparatus has become smaller. The heart reveals the characteristic concentric hypertrophy, with very thick wall and relative reduction in the size of the ventricular cavities. The patient does not live long enough to get an eccentric hypertrophy. Sometimes a glomerulonephritis is grafted upon the so-called "malignant" nephrosclerosis.

The chronic or so-called "benign" nephrosclerosis, which is found in most cases of primary arterial hypertension at necropsy, may become aggravated by failure of the heart or too marked lowering of the blood pressure by vasodilator drugs. These patients with fixed hypertension require a blood pressure around 180 mm. to maintain an adequate renal circulation for the removal of the products of metabolism. The optimum blood pressure is fixed at a higher level than the normal. When the heart fails the kidney decompensates and the patient will develop uremia. I have often demonstrated an increase of the albuminuria and a rise in the nonprotein nitrogen and creatinin of the blood by temporarily lowering the blood pressure with vasodilator drugs. Great care must be exercised to prevent rather than cause a fall in blood pressure in advanced hypertension. Fortunately for the patient the blood pressure is usually fixed at a high level and cannot be lowered even by nitroglycerin or amyl nitrite. When the heart fails from chronic myocardosis, with or without coronary sclerosis and thrombosis, the patient becomes rapidly worse. Hence the heart condition requires careful watching and therapy. Often an accompanying pulmonary emphysema puts an added strain upon the right heart. Acute vascular crises with dangerous sudden rise of blood pressure should be treated with active vasodilator drugs or venesection. The latter may be a life-saving measure in acute right heart failure. The acute vascular crises endanger life by causing cerebral hemorrhage, spasms with cerebral softening, or acute cardiac or renal decompensation.

**Case IV.**—This colored male, age forty-four, was admitted to my service at the Cook County Hospital in October, 1935. The history was obtained from a relative. The patient had been well until six months ago when he complained of severe headaches and attacks of dizziness. He continued to work as a waiter until three weeks ago. He then complained of marked weakness, nausea and vomiting, and drowsiness. At times there was diarrhea. He was brought to the hospital in coma. There was no history of any previous serious illness.

On inspection a whitish powdery deposit was seen on the face, and neck (uremic frost). There were fibrillary twitchings of the muscles of the arms and legs. The reflexes were lively. There was a positive Chvostek sign. The breathing was of the Kussmaul type. The heart was slightly enlarged, measuring  $5\frac{1}{2}$  inches in transverse diameter. The aortic second sound was accentuated. There was a definite pericardial friction rub heard over the entire heart area. There was no evidence of cardiac decompensation. The blood pressure was 275 systolic and 160 diastolic. The urine revealed a specific gravity of 1.012 with albumin, hyaline casts and few red blood cells. The blood chemistry showed a nonprotein nitrogen of 175 and creatinin of 8.5. The eyegrounds revealed a marked hypertensive neuroretinitis.

Because of the short duration of the illness (six months), the very high systolic and diastolic blood pressures, the concentric cardiac hypertrophy, the pericardial friction rub, hypertensive retinitis, high creatinin and nonprotein nitrogen, a definite diagnosis of "malignant" hypertension with uremia was made. To the diagnosis was added uremic pericarditis, and colitis. The necropsy confirmed the diagnosis. The kidneys revealed the picture of a severe malignant nephrosclerosis, with diffuse arteriolosclerosis and necrosis and endarteritis of the arterioles. There was also a uremic pericarditis and enteritis. The heart showed a marked concentric hypertrophy.

#### THE THERAPY OF ESSENTIAL HYPERTENSION

The great variety of therapeutic agents recommended for essential hypertension is the best proof of the unsatisfactory results obtained with most of them. The best result obtainable is to stop the progress of the disease. Much can be done by proper training and conduct to prevent an unfavorable outcome. These patients have a lowered threshold for various stimuli and irritants, which lead to increased vascular tonus. They are very susceptible to psychic influences. Hence psychic therapy is most important of all. These patients require reduced physical activity and mental rest. The benefit of many therapeutic procedures is largely suggestive.

The patient should not become the victim of costly and often worthless medication. We have at present no drug which will bring the condition of the sarcoplasm of the vascular contractile tissues back to a physiologic condition. We have already stated that the cardiac hypertrophy is compensatory and necessary in overcoming the increased peripheral resistance and stasis.

There are two means of reducing the blood pressure: (1) by action on the heart, and (2) by action on the arteries and arterioles. Any agent which affects only one of these factors must endanger the functional capacity of the other. The ideal drug should affect both at the same time, and gradually, not suddenly. We therefore attempt to relieve the heart and at the same time relax the peripheral vessels. Relief of cardiac tension is accomplished by venesection. But this is indicated only in moments of danger, such as pressor vascular crises with acute insufficiency of the heart and pulmonary edema, or marked rise of pressure in cerebral hemorrhage. The effect is of short duration.

Of the drugs sedatives act best by influencing the vasomotor center and lowering vascular tonus. The vasodilators, such as amyl nitrite, nitroglycerin, erythrol tetranitrate, sodium nitrite, etc., are indicated in angina pectoris, cardiac asthma, cerebral vascular spasms, and marked rises of blood pressure. Papaverine and its derivatives are advised by Pal. The xanthin compounds are of value, as they act on the coronary, cerebral, and renal vessels. As a rule they do not cause much drop in blood pressure. Caffeine, theobromine, theophylline, diuretin, theominal, and aminophyllin are the most popular. Their chief value is the dilation of the coronary arteries, also the cerebral vessels.

The diet should be sufficient to maintain the weight at a normal level. A mixed diet of 1500 to 2000 calories is enough. Albumin, purine foods, and salt should be restricted. Fluids should be limited to an average of 1500 cc. daily. There is no evidence that a moderate protein intake has any harmful effect in essential hypertension.

Carefully dosed exercise is beneficial especially for the lazy or obese hypertensive. Proper exercise produces a more economic metabolism and tends to reduce the blood pressure especially in obesity and diabetes. Walking, riding and golf are most suitable. They improve respiration and cardiac activity. Massage is less valuable than carefully controlled active exercise. Baths at 35° to 40° C. reduce blood pressure, those over 40° C. raise the pressure. Warm or lukewarm baths are best. Warm foot baths are very useful in cerebral congestion. Hot turkish baths should be forbidden. Carbon dioxide baths are beneficial with blood pressures below 200. A warm climate and moderate altitude are most favorable. Mild laxatives such as Carlsbad salts, or other saline laxative, are of value.

Finally, a restful régime with reduced physical and mental strain, plenty of rest periods, and at least eight to ten hours of sleep, is the best remedy. Bromides, amytal, or other sedative may be required from time to time. Tobacco should be forbidden or reduced to a small amount. We do not have time to discuss the therapy of the decompensated heart, cerebral hemorrhage, or renal insufficiency.

### OCCULT HEART DISEASE

THERE are cases of heart disease in which the clinical manifestations are so obscure or so atypical that *an underlying cardiac factor is not suspected* as being the cause of the patient's symptoms. Such patients may be said to have occult heart disease because the cardiac factor is obscure. The term is not to be employed as a designation for various congenital or acquired cardiac defects which produce no symptoms nor in connection with the well-recognized fact that the degree of anatomical change frequently is not parallel with the severity of the symptoms. The significance of the term will, perhaps, be appreciated best by the presentation of the illustrative cases of which the following are examples:

The first patient to be discussed was admitted to the hospital several weeks ago. He was a colored preacher fifty-two years of age who complained of severe pain in the left foot three days before admission. The pain became more intense, began to ascend to the leg and involved the opposite foot two days after his symptoms began. There were no other complaints at the time, and there was nothing in the past history which could throw light on the cause of the increasingly severe pain in the feet and left leg. He had been active in his work, was not short of breath and never experienced thoracic discomfort, nor was he aware of any other symptoms which might attract attention to his heart.

Examination revealed a well-nourished, apparently middle-aged colored adult who was obviously in great pain. The left foot showed evidences of dry gangrene, the toes were cold and no pulse could be felt in the lower extremity. The right foot was not gangrenous but was cold and no pulse was palpable in

this limb. There were a few crepitant râles at the right base of the lungs and the apex beat of the heart was slightly beyond the midclavicular line. The heart sounds were regular, of good quality and no murmurs were audible. Systolic blood pressure was 165 mm. mercury and the diastolic was 105 mm. Nothing abnormal was found in the abdomen. The pupils were sluggish to light but the patient had received morphine for pain. The knee jerks could not be elicited. The patient was too ill to be moved for further study and a tentative diagnosis of hypertension with atherosclerosis was made with probable obliterative disease in the vessels of the lower extremities due to thrombosis. Conservative measures were employed while waiting for a line of demarcation to form. Gangrene rapidly extended until both feet and legs and the lower half of the thighs were involved. The patient rapidly became severely toxic and died a few days later and before surgical measures could be employed.

Autopsy revealed embolic occlusion of both tibial arteries with extension downward by thrombosis and a more recent riding embolus was found at the bifurcation of the abdominal aorta. The heart was moderately enlarged and showed an old occlusion of the anterior descending branch of the left coronary artery with large aneurysm formation of the left ventricular wall near the apex. A large mural thrombus filled the inner aspect of this aneurysm in the left ventricle. The thrombus material was soft and presented several pedunculated areas some of which had apparently broken off and were carried by the blood stream as emboli to the lower extremities. There were no other abnormal findings except moderate congestion of the lungs and no other possible source for the emboli could be found.

Here is a classical example of so-called "occult heart disease" which produced no cardiac manifestations but resulted in fatal complications. Careful questioning during life failed to elicit any history suggestive of coronary occlusion or cardiac failure and physical examination revealed very little evidence of heart disease except slight cardiac enlargement. This is not

as rare as is ordinarily supposed and it is common knowledge that healed myocardial infarcts and occlusion of the coronary arteries are not infrequently found at autopsy without symptoms having developed during life. Parallel situations are seen in the finding at autopsy of gallstones or peptic ulcer without symptoms having been present during life to disclose the existence of such lesions. It may be worth while to mention again that coronary occlusion may exist without symptoms or it may produce a variety of clinical pictures not all of which are characteristic. The presence of a healed myocardial infarct as an accidental finding at autopsy may furnish the evidence that such a condition existed without symptoms during life. Sudden death without previous warning in a patient who has never experienced precordial pain is another form in which coronary occlusion may manifest itself. The third group produces the classical picture of substernal or precordial pain, vascular collapse, fever, leukocytosis and the distinctive electrocardiographic changes. There is still another group in which abrupt dyspnea is the first and only sign; no pain being present at any time. There is a rather large number of patients with coronary occlusion in whom gradual cardiac failure progresses and in whom severe pain or dyspnea are not very evident at the onset. Finally, there is a rarer form in which few or no manifestations appear until embolic phenomena occur as the only evidence of the existing myocardial infarct. Our patient is an example of this last form and the condition should be kept in mind in the differential diagnosis of embolic phenomena when the source of the embolus is obscure.

The second example is that of a physician sixty-three years of age who complained of pain in the epigastrium with some radiation to the right side of the abdomen and upward to the chest. The attacks began about two years before admission to the hospital and consisted of severe pain in the region indicated together with nausea, occasional vomiting, and marked weakness. The duration of these symptoms was from a few minutes to several hours and usually left the patient much fatigued and shaken. Jaundice was never observed and fever

this limb. There were a few crepitant râles at the right base of the lungs and the apex beat of the heart was slightly beyond the midclavicular line. The second example is that of a physician sixty-three years of age who complained of pain in the epigastrium with some radiation to the right side of the abdomen and upward to the chest. The attacks began about two years before admission to the hospital and consisted of severe pain in the region indicated together with nausea, occasional vomiting, and marked weakness. The duration of these symptoms was from a few minutes to several hours and usually left the patient much fatigued and shaken. Jaundice was never observed and fever

was absent but definite tenderness in the right upper quadrant of the abdomen was a frequent finding. A diagnosis of cholecystitis with probable gallstone colic was made by his physician and surgical treatment was advised. Roentgenological examination did not reveal any abnormality in the gastro-intestinal tract. Cholecystography furnished no decisive information and plain films of the gallbladder failed to disclose evidence of disease of the biliary tract. The patient wished to remain on medical management for a while and decided to go to the west coast for a vacation. He made the trip in a leisurely manner and observed with satisfaction that his symptoms improved. While sojourning at a high altitude he decided to do some mountain climbing, a sport in which he engaged for several days. The pain in the upper abdomen became much worse abruptly and persisted for two days. Hypodermic injections of morphine were required to induce some degree of comfort. Dyspnea and collapse now became evident. His blood pressure fell from the usual level of 140 mm. mercury to 94 mm. and an easily recognizable picture of coronary insufficiency was now apparent. An electrocardiogram was not available at the time but the patient remained in bed for eight weeks during which time he was treated as a case of coronary occlusion. He subsequently returned to his home but cardiac failure was now evident and attacks of pain recurred at irregular intervals until sudden death ten months later.

Autopsy revealed a fresh occlusion of the anterior descending branch of the left coronary artery and several old occlusions in both the right and left coronary arteries. The liver showed evidence of moderate fibrosis and chronic passive congestion but the gallbladder and biliary passages were normal.

It is a question, of course, whether electrocardiographic studies at the onset of the symptoms would have revealed the true nature of his illness. The accuracy of this diagnostic procedure has been increased with the introduction of the fourth lead but we have seen patients with anatomical occlusion of the coronary artery in whom careful electrocardiographic studies sometimes failed to show evidence of this condition.

It is possible that more careful questioning of the patient would have revealed the information that the abdominal pain also radiated under the sternum as well as elsewhere to the chest. Also, that some degree of thoracic oppression occurred or that dyspnea was experienced during the attack. It would be of interest to know if the upper abdominal tenderness was circumscribed or whether it was diffuse over the entire liver region as one would expect in acute attacks of passive congestion of the liver. The occurrence of abdominal pain in cardiac disease also brings up the question whether some of the cases of so-called "abdominal angina" are actually due to atherosclerosis of the mesenteric arteries even if they were found at autopsy to be involved in a high degree. The fact that the abdominal symptoms completely dominated the clinical picture in this case of coronary disease is an example of the care necessary in excluding obscure clinical pictures of coronary disease in patients past middle age.

The diagnostic difficulties are, of course, increased when gallbladder pathology coexists with coronary disease. One must then weigh the part played by each and also whether surgical removal of the biliary tract disease can be undertaken with safety because very gratifying results have been obtained by such a procedure. Surgical treatment in such instances has resulted not only in amelioration of abdominal symptoms, but the cardiac difficulties have also frequently been greatly improved.

Time and space prevents us from presenting further cases of so-called "occult heart disease." It is not our intention merely to coin a new phrase for an old conception. Our purpose is to remind the physician that heart disease can masquerade as some other illness, that there may be no obvious cardiac manifestations until a very exhaustive study is made from the cardiovascular standpoint and that such conditions will be recognized more frequently if such possibilities are kept in mind. There is a great deal of truth in the axiom that we diagnose the conditions we think of and miss those which are not taken into consideration while deliberating on a differential diagnosis.

## CLINIC OF DR. CLEVELAND J. WHITE

DEPARTMENT OF DERMATOLOGY, NORTHWESTERN UNIVERSITY  
MEDICAL SCHOOL

---

### TREATMENT OF CHRONIC LEG ULCERS

ULCERS of the extremities often present a difficult problem for diagnosis and hence the proper therapy. The recent literature has been quite full of new forms of treatment for various types of ulcers. The dermatologist is often consulted in regard to diagnosis while many of the therapeutic procedures are distinctly in the realm of the surgeon and better handled by surgical methods.

#### VARICOSE ULCERS

One of the most common types and one which gives considerable trouble in treatment is the ordinary varicose ulcer and its complications. The clinical picture of varicose ulcer is very well known. The location is usually on the lower half of the legs at the inner aspect and above the malleolus. The ulcer is usually single and usually surrounded by lichenified callous border. The uncomplicated varicose ulcer is best handled by applying an Unna boot. All are acquainted with this type of boot, and I just wish to emphasize it in stating that it is still our best method of treatment, by giving rest to the area of the ulcer in order to bring about healing. After healing has taken place the obliteration of the varicosities is in order.

Since the injection method has come into vogue, surgical removal has practically vanished as a method of therapy in the ordinary case. The type of fluid used in injection varies in the different clinics, but it has simmered down pretty well to potassium oleate, sodium morrhuate, glucose, quinine, urethane,

sodium salicylate and sodium chloride. Different statistics are given for the various types of injection, but the main indication for success in these varicosities is proper technic, with the proper selection of suitable cases. De Takáts uses potassium oleate in 5 and 10 per cent strength, and reports excellent success in a large percentage of cases. Some of the large clinics use elastic plaster in place of the Unna boot. Douglas has

Fig. 12.—Varicose ulcer.

recently reported his results and believes that it answers the purpose very well. In some 90 cases he got prompt healing in almost 97 per cent. Whether the Unna boot or the elastic plaster will be used depends upon the individual's skill in handling the method.

The complications of the injection method of treating varicose veins are well known and have to be considered in using this method. The three most common complications are

phlebitis, thrombosis, and thrombophlebitis, which Zimmerman has discussed in detail.

Ulcers of the extremities associated with varicosities which are found below the malleolus are oftentimes due to failure of the deep saphenous vein. Here de Takáts has been foremost in advocating the ligation of the vein in order to produce a healing in this stubborn type of ulcer.

It hardly needs to be reiterated that in varicose ulcers associated with superficial infectious dermatoses, either bacterial or fungus, it is necessary to use applications to cure the dermatological features before active measures are taken to heal the ulcer.

#### PHAGEDENIC ULCERATIONS

Another type of ulceration which has been attracting more and more interest not only because of its rarity but because of its stubbornness in yielding to treatment is the so-called "phagedenic ulcer." This type is apparently becoming more common. After a minor infection, as on a toe, or after drainage of an abscess, as of one of the inguinal lymph nodes, there occurs a slow but insidiously progressive destruction of the skin. It has been a baffling problem because none of the usual bactericidal agents, either chemical or physical, seems to exert the slightest influence on this infection. It is characterized by remarkable chronicity, and until its final stages it is usually not attended by severe constitutional symptoms. However, since Cullen has emphasized the value of the cautery and Baer's application of maggots in this type of infection, a satisfactory method of treatment has been evolved in most cases.

Holman of the Department of Surgery of Stanford University has analyzed several cases in which the method of treatment is very instructive. In one of his cases an axillary abscess followed a small blister of the left hand which had been opened and exposed to animal fertilizer. In the original culture only hemolytic streptococcus was recovered, but after eleven months of steady progression and secondary ulcerations of the chest, *Staphylococcus aureus* was recovered in culture as well as the other organisms. In this particular case no response to

therapy was had until the maggot treatment was used. The combination of these two organisms has been emphasized by Meleney in various writings. Meleney designates this disease process as a result of a bacterial synergism and believes a synergistic bacteriology of certain types of bacteria causes this progressive gangrene of the skin. Cases involving especially the inguinal region demand an early recognition of the irresistible character of this type of infection, and even bold surgical excision of the overhanging edges occurring during the infection to prevent involvement of the large blood vessels.

Holman cites another case of trivial injury of the fingers followed by extensive abscess of the axilla which had progressed for nine months' time. Finally streptococci and anaerobic staphylococci were recovered, whereupon he instituted extensive and thorough cautery *débridement* and maggot treatment in addition to blood transfusion and high vitamin diet.

#### TRAUMATIC AND ANEMIC ULCERS

Ulcers which occur after trauma at times present a very difficult situation. Rest and various other measures have been used, together with different applications. The use of sulphydryl, containing the amino-acid cysteine has been used by Brunsting and Simonsen with marked success in this type of case. Others have used cod liver oil as wet dressings.

Recently R. A. Jacobson has been using ordinary sterile vaselin with the ulcer completely covered with the Unna boot, following Orr's method of treatment of osteomyelitis, with success. Saylor and others have used acetylbetamethylcholine chloride iontophoresis in the treatment of chronic ulcer especially the varicose type.

#### ULCERATIONS IN PERIPHERAL VASCULAR DISEASES

Ulcers of the extremities occur in the chronic peripheral circulatory diseases. It is important to differentiate between the functional and organic types.

**Functional.**—Vasomotor disturbances consist of a vasoconstrictor and a vasodilator nature. Raynaud's disease is an

example of the vasoconstrictor disorder and erythemomyalgia, of the vascular spasm type. This latter type never ulcerates. In the second group organic insufficiency is due to the occlusion or diminution of the lumen of the blood vessels. In this group thrombo-angiitis obliterans or Buerger's disease and arteriosclerotic endarteritis obliterans are two important clinical divisions. In this organic group pulsations of the peripheral vessels are diminished or absent. These are the dorsalis pedis and posterior popliteal in the leg and foot. When pulsation in

FIG. 13.—Thrombo-angiitis obliterans (Buerger's disease).

the main vessels is absent or diminished the extremity becomes red in color when dependent and naturally blanched with elevation. Trophic changes followed by gangrene usually occur unless the various types of treatment are instituted. In the case of thrombo-angiitis obliterans immediately preceding or following trophic changes, the pain is continuous and excruciating and in the past amputation has been necessary for relief. In the arterio-sclerotic group pain is not a very prominent feature and there is no associated, recurrent superficial phlebitis

as in thrombo-angiitis obliterans. While so-called "Buerger's disease" has been mainly found in the Jewish race and in the male sex, there are now ample statistics to show that it occurs in other races, and in the female sex. In the arteriosclerotic type x-rays of the extremities will show calcareous deposits in the blood vessels. The disease usually occurs after the age of fifty-five, whereas thrombo-angiitis obliterans usually occurs between the ages of seventeen and fifty.

A great deal of interest has been shown in the treatment of Raynaud's disease in the past few years by the institution

Fig. 14.—Endarteritis obliterans. Woman, aged seventy-two, with ulceration of nine months' duration. The peripheral circulation is occluded, and the extremity cold and clammy.

of surgical methods, namely, periarterial sympathectomy. Which has led to sympathetic ganglionectomy to secure the best results. Most clinicians agree that the essential vascular disturbance in Raynaud's disease is arterial spasm. However, there is some disagreement as to which types of cases should be subjected to sympathectomy. The recent work by Crisler and Horton on the effect of fever on the digits has been used to differentiate between thrombo-endarteritis obliterans and Raynaud's disease. About one third of the patients with thrombo-endarteritis obliterans had color changes, red, white

and blue, which indicated vasospastic disorder. However, these workers feel that the vasospasm which gives rise to the color changes is secondary to or superimposed upon an organic occlusive disease of the arteries. Their work emphasizes the primarity of organic changes in thrombo-endarteritis obliterans and of functional changes in Raynaud's disease. Until the advent of periarterial sympathectomy the treatment of Raynaud's disease has been very ineffective. The use of this surgical procedure should be seriously considered to avoid the advanced gangrenous stage.

In the treatment of thrombo-endarteritis obliterans all clinicians advise conservative measures. Silbert, of New York, has had excellent results with the use of hypertonic salt solution intravenously. He has recently reported a large series of cases which emphasize the successful results following the use of this conservative measure. The diagnosis of a situation of this type and treatment will prevent the cases that used to go on to amputation, which is a serious economic handicap in this group of usually young men. Sodium citrate has been used by other workers. Other methods have as their basis the increase of the peripheral circulation, such as the postural exercises of Buerger, the application of dry heat, and the cessation of tobacco in every form. In an excellent critical review of the recent literature on surgical treatment of peripheral vascular disease, Scupham and de Takáts feel that sympathectomy in patients with Buerger's disease is best limited to the upper extremities when digital gangrene and intractable pain are present. This is based on the premise that relief from pain in the extremities, excluding amputation, can be obtained by other measures. In patients in the forties paravertebral alcoholic injections are occasionally of benefit.

The treatment of the arteriosclerotic group has not been so successful. While the occasional case is associated with diabetes, syphilis, lead poisoning, etc., usually no such etiology is discovered, and general arteriosclerotic measures have to be used. Recently mechanical improvement of the circulation by passive vascular exercises has been of material assistance in

these types of cases. In a recent monograph on passive vascular exercises, Louis G. Herrmann emphasizes the value of conservative management of obliterative arterial diseases of the extremities. When gangrene appears, then amputation is necessary, whereas in thrombo-angiitis obliterans amputation is now becoming rarer (9 per cent in Silbert's series). De Takáts emphasizes that in cases of diabetic gangrene an important distinction has to be made between the condition that is primarily due to deficient circulation and that which is primarily due to infection. Naturally both conditions may be present. While the former demands a major amputation, the latter is solved by minor amputation or sufficient drainage. In the gangrenous state of older patients, especially in those with diabetes, conservatism must not lead to unnecessary delay in facing inevitable amputation. Tests are quite accurate now to determine the collateral circulation to ascertain the level for amputation. In a woman of seventy-two, who was recently observed, the ulceration appeared just at the distal extremity of the small toe of the left foot. Early recognition and conservative management usually will save the extremity from amputation.

#### ULCERS DUE TO INFECTIONS

Infectious ulcers of the extremities are quite well known. The ordinary superficial fungus infection (ringworm) with secondary infection can cause an ulcer, especially where there are organic peripheral circulatory disturbances. Several of this type of case have been observed. In these, sodium citrate treatments have been used intravenously to help to increase the circulation, while local fungicidal preparations are used as local applications.

Ulcers of late syphilis can occur on any part of the extremities, but more often at the sites of trauma, for example, of the knees. Clinically, the findings have been those of ulcerating gumma; the clinical stages have been emphasized again and again by Stokes. His 10 salient features of diagnosis of late syphilis are present in one form or other. He emphasizes the solitary character, the asymmetry, the indurated infiltra-

Fig. 15—Epidermomycosis ("ringworm") of foot with secondary infection and ulceration of leg.

Fig. 16—Nodulo-ulcerative syphilis (tertiary lues).

tion the indolence, the arciform configuration, sharp margins, tissue destruction, peripheral extension and superficial

atrophic scarring with peripheral hyperpigmentation. While the serology is usually positive to support the clinical diagnosis of nodular or ulcerative syphilides, the clinical characteristics are usually so apparent that the serology is only confirmatory. Occasionally the ulcerating gummatous area will be accompanied by a satellite lymphangitis, as observed in Stokes' clinic several years ago. Furthermore, with secondary infection the patient may have definite fever of intermittent character.

Fig. 17.—Mal perforans. Woman, forty-two years of age, with positive blood and spinal fluid serology, with neurological findings of tabes dorsalis and ulcerations of fifteen months' duration.

Ulcers of the extremities due to tuberculosis are usually of 2 types, either a primary inoculation of tuberculosis following injury or ulcers of the calves of the legs, called erythema induratum. At the onset, a tuberculous ulcer is manifested by one or several ulcers of dusky red color which become lighter when the ulcers have a jagged border. Histological section of a border of a tuberculous ulcer is the typical histology of tuberculosis and is easily recognized. If a tuberculous ulcer heals the scar is thickened and hypertrophic as compared with the thin, atrophic cigarette paper scar of a late syphilide. The

treatment of tuberculosis of the skin has taken on additional interest since the institution of dietary measures, especially those suggested by Gerson of low starch and low salt. Other workers have made minor modifications and the results have been striking in numerous cases.

Erythema induratum is manifested on the posterior portion of the legs by bluish-red nodules followed by ulceration. They are of a symmetrical character and oftentimes come in showers. While histological section will not show a typical tuberculous nature, sufficient clinical studies have been carried through which substantiate the tuberculous origin from some focus in the body, either visceral or glandular. Direct proofs by guinea-

Fig 18.—Erythema induratum (a tuberculous entity).

pig inoculation have been found by several workers. It usually occurs in youthful individuals, especially in young girls. Such a patient was recently observed: she felt that an industrial injury was the cause but there was no basis for such a supposition.

Ulcers of deep invading fungi are well known. The ulcers of blastomycosis have characteristic pinpoint abscesses in the ulcer border. Actinomycosis does not occur on the extremities very often. This diagnosis is substantiated by finding actinomycetes in the purulent discharge of the draining abscess.

Maduromycosis, which is manifested by large nodules which become purulent and have a discharge of small seedlike growths of both black and white color, is another form of ulcer.

So-called "Madura foot" is very uncommon in the United States, though a recent case has been reported by K. L. Puestow.

Sporotrichosis seldom occurs on the lower extremities, as the initial lesion is practically always traumatic on the digits, forming a sporotrichotic chancre with a cordlike lymphangitis extending to the extremities. The rare constricting ulcer of the toe, so-called *ainhum*, practically never occurs in this country. It is a constricting band which gradually causes ulceration and amputation of the digit.

#### MALIGNANT ULCERS

The occurrence of ulcers by malignant growth is, I believe, becoming more common, especially those of the pigmented mole type. The ordinary basal-cell epithelioma with a pearly border and central ulceration and peripheral growth (the so-called "rodent ulcer") very seldom occurs on the lower extremities. Squamous-cell epitheliomas occur following injuries, and at times are primary growths. Here the ulcer is deep seated, the border advances rapidly, and soon there is invasion of the adjacent lymph nodes by metastases. The squamobasal cell type, which histologic picture has recently been emphasized by Montgomery, has usually been found on the trunk. A diagnosis of squamous-cell epithelioma with confirmation of the clinical findings by histologic section should be dealt with by drastic surgery. Electrosurgical removal is the treatment of choice for both the basal and squamous-celled type; radium can be used in the older patients. In a thorough study of 61 cases of squamous-cell epithelioma of the extremities, DeBere and Stevenson found that metastases to regional lymph nodes occurred only in the large growths, usually larger than 3 cm. in diameter.

The occurrence of pigmented moles, especially the bluish-black type, is often seen, especially on the toes. No etiologic information can be ascertained in the average case, the bluish mole appearing in conical form and growing in a site that is subject to irritation. Conservative dermatologists recommend

radium if the lesion is not too large—not over a  $\frac{1}{4}$  of an inch in diameter—because surgical excision is unsatisfactory due to the possibility of melanoblasts being found inches away from the original lesion. Surgical interference in such a predicament may lead to rapid dissemination. In several cases, however, radium has had no effect even in large doses, and surgery was necessary in competent hands, with excellent results. The occasional occurrence of sarcoma calls for histologic study of normal growth in order to detect malignancies in their incipency. A case was recently observed in the practice of Dr. C. W. Yarrington where extensive melanocarcinoma were present and no primary lesion could be determined.

#### X-RAY BURNS

Ulcers produced by excessive x-ray treatment are only too common. One of the most extensively involved cases is that of a young woman who had x-ray treatment in a so-called “hair-removal” institute for hypertrichosis of the lower extremities. Here the large ulcers of the legs were accompanied by severe and intense pain. The indicated treatment is that of skin transplants by surgical methods.

Some hope has been given recently in small x-ray burns by using aloe vera in 50 per cent ointment which in many instances encourages epithelialization, decreases the pain and allows the small ulcer to heal. The use of the ointment is much more satisfactory than the aloe vera leaf which was first advocated. Ulcers from radium, like those from x-ray, can be prevented when the radium is used with ordinary skill.

#### EXTRAGENITAL VENEREAL ULCERATIONS

Veneraeal ulcers as chancroid, granuloma inguinale and lymphogranulomatosis of Nicolas and Farre can occur on the extremities, especially the chancroid type. These ulcers have a soft base, are usually multiple, and at times are distinctly difficult therapeutic problems. Actual cauterization has been advocated and in some cases it is necessary to use tartar emetic intravenously to procure results. Lymphogranulomatous lesions usually are associated with strictures around the rectum.

Here the diagnosis may be confirmed by a positive Frei test. Beginning with a nodule on the glabrous skin, the granuloma inguinale lesions spread in the form of an ulcerative granular patch. The borders are distinct and the surface is riddled with papillomatous elevations. The center gradually becomes cicatrized.

#### FACTITIAL ULCERS

Ulcers produced by the patient either because of mental derangement or for the purpose of creating sympathy or increasing compensation must be kept in mind. Their annular and geometric configuration usually betray their origin, even if it is difficult to discover any trace of the material used. A young woman of twenty-two, recently observed, had a deep-seated ulcer of the extremity and one in an appendectomy wound of the abdomen. The occurrence of lesions on the body, especially ones she was able to produce with the right hand, finally proved the origin of these multiple ulcerations. While such ulcers have been described, it is rare to see such a lesion on the abdomen reaching practically to the peritoneum. In this case it was produced by phenol. The patient was able to disengage in the practice after the true cause was related to her. In patients with mental aberrations, it becomes a case for psychiatric treatment.

#### MISCELLANEOUS

Ulcers of the extremities, associated with general conditions, are quite well known, the most common being in the sickle cell anemia. They occasionally occur in multiple sclerosis and as a sequel of encephalitis. Even ulcers following typhoid and preceded by arteritis have been reported. Garvin and Trumess have reported ulcers due to localized allergy.

Ulcers and granulomatous lesions following the ingestion of halogen salts, such as iodides and bromides, are characterized by a vegetative appearance and the history of the ingestion of such medicament. Some cases occur after taking bromo-seltzer in which the victim is not aware that bromide is being taken.

Ulcerations occurring in the malignant lymphoblastoma group, as granuloma fungoides, the leukemias and Hodgkin's disease, are usually diagnosed by other corroborative clinical findings and microscopical studies.

Ulcerations occur on the feet and lower extremities due to industrial pursuits. Such have been reported in workers due to chrome and lime, fumes of hydrochloric acid and hydrofluoric acid and shale oil.

## CLINIC OF DR. LUKE W. HUNT

ALBERT MERRITT BILLINGS HOSPITAL

---

### THE DIAGNOSIS AND TREATMENT OF FIBROSITIS AND MYOSITIS

#### FIBROSITIS

FIBROSITIS is an inflammation of white fibrous tissue and may, therefore, occur in many parts of the body—in fascia, aponeurosis, sheaths of muscles and nerves, tendons and ligaments, articular capsule, periosteum and subcutaneous tissue or any part where fibrous tissue is found. Although widely recognized abroad, fibrositis has received but scant attention in this country, and many American monographs on rheumatic diseases fail to mention it or devote very little attention to the condition. Nevertheless fibrositis is common, and is responsible for many painful conditions often termed myalgia, muscular rheumatism, neuritis and so forth. To designate the involvement of special parts certain terms are employed, synovitis, tenosynovitis, bursitis, and perineuritis, etc. The two most common forms are the intramuscular and the periarticular. The former may be localized as in lumbago, torticollis and pleurodynia or diffuse as in generalized muscular rheumatism. Periarticular fibrositis may affect the capsule of the large joints or many small joints. In any of these situations it is usually acute at first, but may become subacute or chronic, the last being more common in later life.

**Etiology.**—The essential cause of fibrositis is infection in the great majority of cases, and usually from a local focus. Many investigators believe streptococci responsible while others incriminate unidentified or other toxins. English writers believe that under certain conditions of irritation the fibrositis nodule introduces toxic material into the circulation when the

original focus of infection has long been removed, and that it has itself become a focus, secondary to the infecting focus but needing no reinforcement for its effective existence. Trauma, muscular strain and exposure to cold and damp are predisposing factors, especially in acute attacks. Prolonged strain on tendons and ligaments may be responsible for a chronic fibrositis but infection is often superimposed. It may follow exposure to a draught of air or sudden chilling after heavy exertion may bring on an attack. One attack renders an individual more liable to subsequent attacks. Individuals with gout seem prone to fibrositis. Chronic alcoholism or lead poisoning may be etiological factors.

**Pathology.**—The essential pathological characteristics of fibrositis are a diffuse and localized inflammatory hyperplasia of fibrous tissue. The localized lesions may be palpable as nodular tender regions of infiltration in muscles or near the attachment of tendons. In acute cases there is a serous exudation in the affected parts, and following this there may be proliferation of the fibrous tissue. This may extend between the muscles and cause stiffness and pain. Disability with muscular atrophy may result.

**Symptoms.**—The symptoms and physical findings, and method of arriving at a diagnosis are illustrated by this patient, a forty-one-year-old male, a plumber, who came to the clinic complaining of pain in the lower part of the back of three weeks' duration. He had enjoyed good health all his life except for a similar attack which lasted for two weeks about six months ago. The night before the present attack the patient played hand-ball and perspired freely. He does not remember that he injured his back at that time. The next morning he awoke with pain and stiffness in the lumbar region. The pain was a dull ache but became sharp and severe when he stooped or turned his body. It did not radiate. There is no history of a cold or sore throat before the onset. He remained in bed. applied heat with slight relief but the condition has persisted. He does not think he has had a fever.

The past history, family history and inquiry by systems

are essentially negative. Upon physical examination we find this patient to be a well developed and nourished muscular individual who does not appear acutely ill. The temperature is 99.2° F. The pupils are equal, regular, and react to light and accommodation. There is no lid-lag or exophthalmos. There is no discharge from the nose, and no pain over the sinuses. There is no discharge from the ears, the drums are normal. The tongue protrudes in the midline, there is no tremor. The teeth show a good deal of dental workcrowns and large fillings. There is retraction of the gums around the crowns. There is no lead line. The tonsils are out, the pharynx is not injected and there is no postnasal drip. The thyroid is not enlarged, there are palpable, tender anterior cervical glands on the left. The lungs are clear to auscultation and percussion. The heart border is 9 cm. from the midsternal line. There is a soft systolic murmur at the apex, not transmitted.  $P_2 > A_2$ . The blood pressure is 130/80. The abdomen is flat. There is no tenderness or masses. The liver, kidneys and spleen are not felt. There is no hernia. The knee jerks, triceps, biceps, Achilles reflexes are present and equal. There is no ankle or patellar clonus. Romberg is negative. Flexion of the thigh on the abdomen and extension of the leg causes pain in the lumbar region. There is no tenderness over the sacro-iliac joints. When the thigh and knee are flexed and the external malleolus is placed above the patella of the opposite leg, depression of the knee causes no pain in either hip. There is tenderness of the lumbar muscles on both sides. Tender areas are found just above the iliac crests and lateral to the spine but no definite nodules are felt. The patient has difficulty in turning on his side and cannot assume a sitting position unless he is assisted. There is no scoliosis. There is no tenderness to pressure or percussion over the spinal processes. The arches of the feet are normal. Rectal examination reveals good sphincter tone, the prostate is smooth, firm, not enlarged but slightly tender. The seminal vesicles are not tender. Pressure on the sacrum and coccyx causes no pain. The Wassermann and Kahn tests are negative. The leukocyte count is 10,700,

hemoglobin 88, red blood cell count 5,250,000, urine specific gravity 1.015, no albumin, no sugar, occasional leukocyte. Microscopical examination of the prostatic fluid shows an occasional leukocyte. x-Rays of the pelvis and lumbar spine are normal. x-Rays of the teeth show two lower molars on the left with periapical lesions, and a right upper molar with incomplete root canal therapy.

From the history, symptoms, physical findings, laboratory examination and x-ray findings it is very likely that this patient has an acute fibrositis of the lumbar muscles. The predisposing factors are probably an injury and exposure to a draught, and superimposed is a dental infection.

**Diagnosis.**—In attempting to arrive at a diagnosis of a patient with such symptoms one can usually detect those cases that are due to a systemic disease by observing that the patient not only complains of pain but looks acutely ill. If he does so, and his temperature is 100° F. or higher, it is quite likely that one is dealing with a systemic condition at its onset or perhaps it may be a meningitis, an acute myelitis or even an acute rheumatic process, and in all of these, the pain in the back is only an obstrusive symptom to which will be added some of the signs distinctive of the disease. Often, however, as in this case one has to deal with a patient who, except for the pain in the back, is comparatively well. In such cases it is advisable to ask the patient how it arose—for example: did it follow a blow or some unusual exertion or unintentional movement? Then the duration, if it is constant or intermittent, and if it radiates. Inspection may reveal a skin condition such as herpes, swelling or redness or undue prominence of a spinal process, bruises or purpura or atrophy of muscles may be apparent. Inspection may also reveal any abnormality of the spine. Palpation may reveal tenderness on pressure of muscle or bone, it may show fluctuation, hyperesthesia of the skin or fibrositic nodules or cords. The next step is to test for disease of the bone by tapping each spinal process with a percussion hammer, jar the heels alternately with the legs held rigid, and note whether pain is elicited. Then one may find if pain is

caused by movements of any kind—flexion, extension, abduction, adduction and rotation. Careful examination of the abdomen for tenderness or masses, and lastly x-ray examination of the painful area should be done. Careful search for foci of infection should be made. By such an examination an etiological diagnosis can often be made.

**Differential Diagnosis.**—Other forms of fibrositis which are likely to be acute at the onset are torticollis and pleurodynia. Pain and stiffness of the neck occur in a number of different diseases and the significance may be grave or trivial. It is not right to assume that the condition is trivial without a thorough investigation. When due to fibrositis it usually affects the muscles of the anterolateral or back region of the neck, is most often unilateral and occurs most frequently in the young. The patient holds the head in a peculiar manner turned to one side, and rotates the whole body when attempting to turn it. Exposure to cold or sleeping in a cramped position may give rise to a transient stiff neck associated with no other symptoms. Often in such cases there is a history of the patient waking up in the morning with a stiff neck, and frequently one will find a latent focus of infection in the teeth, throat or sinuses. The affection of the muscles of the head and neck may be associated with headache, the so-called “indurative” headache.

Pleurodynia involves the intercostal muscles on one side, and in some instances the pectorals and serratus magnus. This is a very painful form of the disease as the chest cannot be at rest. A deep breath or coughing causes pain, sometimes over a limited area. Tenderness of the affected muscles may be the only physical sign present, and it is important that graver mischief such as pleurisy, pneumonia or aortic aneurysm be excluded before a diagnosis of pleurodynia is made. It may be difficult to distinguish from intercostal neuralgia in which the pain is more circumscribed and paroxysmal, and there are tender spots along the course of the nerves. It is well to remember that fibrositis nodules in the left sixth interspace may give rise to pain described as under the heart which may be

mistaken for cardiac pain. Fibrositis in the right axilla in the fifth to seventh interspaces may cause epigastric pain simulating that of duodenal ulcer, and fibrositis nodules in the interspaces from the eighth to the eleventh may cause attacks of pain felt over the abdomen which may be mistaken by the physician or by the patient for pain arising in the colon or in the appendix. In the latter instance the differential diagnosis must sometimes depend to a certain extent upon the presence of tender nodules in the intercostal spaces and the fact that pressure upon them will cause an immediate reference of pain to the abdomen or an attack of pain.

In generalized intramuscular fibrositis, often referred to as common muscular rheumatism, the symptoms are usually an aching stiffness in one or many regions, and soreness or tenderness which are often characterized by migration and frequency of remission. The pain is altered by seasonal and climatic conditions. Fatigue is often a marked symptom. Often the pain and stiffness are worse on arising or after a period of rest or inactivity. Tender spots and nodes the size of a grain of wheat or larger, associated with subcutaneous thickenings may be palpated particularly along the origin of muscles in the lumbosacral, gluteal, or the cervical, upper thoracic or trapezius regions. These nodes and fibrous thickenings are considered the sign posts of the disease. English writers particularly stress the diagnostic importance and apparent ease of finding nodules. Some insist on their presence for a diagnosis; others admit that in many cases of fibrositis no nodules are felt.

In the periarticular type of fibrositis the pathological process affects chiefly the fibrous capsule and the surrounding ligaments. The synovial membrane, which after all is the inner lining of the capsule, may be affected to a more or less extent but pannus formation and invasion of cartilage and articular bone do not usually occur. It is likely that fibrositis is present to a certain extent in every case of chronic rheumatoid arthritis but, fortunately, every fibrositis does not have an associated or eventual arthritis.

The symptoms and physical findings of periarticular fibrositis are well illustrated by this thirty-eight-year-old male who comes to the clinic complaining of pain in the left knee and in the left hip of two years' duration. He was born in Scotland, and has had good health all his life except for the present illness. The pain was first noticed in the left knee and about a week later in the left hip. The pain is a dull ache, is not present during ordinary degrees of motion or when he is at rest. Overuse of the joint or any untoward movement causes pain. There is a good deal of stiffness associated but there has been very little limitation of motion. There has been no swelling or redness of the joints. He tires easily and feels exhausted toward the end of the day. During the past two years he has had two or three periods varying from a week to three weeks during which time he has had very little discomfort. He was told by a physician that he had rheumatism and received several injections of vaccine but with no benefit.

The essential physical findings are: the sinuses are clear, the teeth are removed, the tonsils are enlarged and cryptic; pus can be expressed from the left, the pharynx is injected. The lungs, heart and abdomen are normal. The prostate is smooth, firm, not enlarged and not tender. The reflexes are normal. The left knee is not swollen, there is no redness or crepitus. Just above the left patella there is marked tenderness and a small firm tender nodule the size of a pea, and 2 smaller ones about the size of grains of wheat can be palpated. These nodules are exquisitely tender. There is slight tenderness over the medial surface of the left knee. Extreme flexion and extension of the knee causes pain. There is no redness or swelling about the left hip. There is free motion at the hip but abduction and flexion of the thigh causes pain just below the iliac crest. Pressure in this area reveals tender spots but no nodules are felt. There is tenderness just lateral to the sacro-iliac joint. x-Rays of the left knee and of the pelvis are normal. The Wassermann and Kahn tests are negative, urine normal, prostatic fluid clear. The leukocyte count is 9200, red blood cell count 4,820,000, hemoglobin 86. Cultures from

the nose showed *Staphylococcus albus* and from the throat *Streptococcus viridans*.

From the symptoms, physical findings, course of the disease and laboratory and x-ray findings, it is likely that this patient has a periarticular fibrositis involving the left knee and left hip.

In the early days or weeks of a periarticular fibrositis it may be difficult if not impossible to be certain that a true rheumatoid arthritis is not impending. In periarticular fibrositis manifestations of systemic change are few or absent; loss of appetite and weight, anemia, and general debility are seen to a much less extent than in arthritis. The joints themselves are less tender in fibrositis than in rheumatoid arthritis, and in fibrositis the swellings are absent or slight and x-rays show no articular disorganization over a period of time.

There are no laboratory data distinctive of fibrositis.

**Treatment.**—The treatment of fibrositis depends to a large extent upon the cause, and in every case the effort should be made to arrive at an etiological diagnosis, as only then is proper treatment possible. The three most effective therapeutic measures are: (1) elimination of foci of infection, (2) rest, (3) physiotherapy. Foci of infection are usually apical dental infections, pyorrhea alveolaris, infected tonsils, infected nasal sinuses, pyosalpinx, cervicitis, prostatitis, septic seminal vesicles and occasionally cholecystitis or bowel infections. Careful search for these foci of infection should be made and proper treatment given.

Rest is one of the most valuable therapeutic agents, and should be prolonged as long as conditions warrant. Fixation by strapping should be done wherever possible. The reduction of occupational or other trauma is important. Heat is usually effective in relieving the symptoms, and is perhaps best supplied by an infra-red lamp or an ordinary electric heater for an hour two or three times a day. After the use of the heat lamp gentle massage with equal parts of oil of wintergreen and olive oil or some mild counterirritant is of value. Hot baths are useful. The salicylates are usually effectual in alleviating the acute symptoms, perhaps best given as sodium salicylate to-

gether with calcium gluconate a gram of each four times a day. If the pain is severe and agonizing, the opiates may have to be resorted to temporarily. The bowels should be freely opened, and large amounts of water and fruit juices taken. In the chronic conditions building up the general health by an adequate diet, fresh air and sunshine is often effective. Persons subject to the condition should be warmly clothed, and avoid if possible, exposure to cold and damp.

English workers report good results in the treatment of fibrositis in the subacute and chronic stages by forcibly breaking down the fibrositic cords and nodules by manipulation. The object of the manipulation treatment is to burst the nodule by a sudden and forceful pressure of the finger tips which is calculated to tear asunder the agglutinated fibers. This can be done by combining a rapid to and fro movement with the pressure. This treatment can only be adapted where the cord or nodule can be compressed against subjacent bone, and also where no structure occurs such as nerves and tendon sheaths that might be damaged by the force used.

The use of vaccines in the treatment of fibrositis is usually unsuccessful, although English workers report good results by injecting a lipovaccine (polyvalent streptococci isolated from rheumatic patients and suspended in sterile olive oil) into the inflamed tissue. Fever therapy may help in some cases but too much cannot be expected from its use.

### MYOSITIS

Myositis is an inflammation of the muscles; the voluntary muscles are alone affected in all the varieties except the two known as dermatomyositis and polymyositis haemorrhagica when the heart muscle is also implicated. Myositis has long been known as a primary or secondary disease. The myositides which occur in septicemia, ulcerative endocarditis, trichiniasis, actinomycosis, gonorrhea, pneumonia, typhoid and syphilis are plainly of secondary origin. Primary myositis occurs as an acute, subacute or chronic affection and is seen in two chief forms—the suppurative and the nonsuppurative.

**Primary suppurative myositis** is sometimes single but generally a multiple muscle inflammation, mostly acute, of bacterial origin, presenting the picture of an infectious disease and generally ends in suppuration. Various organisms of the pus-producing type have been isolated but most workers find *Staphylococcus aureus* in every instance. Small infected wounds, furuncles, acne pustules, etc., may serve as the original portal of entry, and apparently the mucous membrane may also at times act in this capacity. Muscles may be made susceptible of invasion by trauma, overexertion, or hyperemia.

Three principal varieties of primary suppurative myositis are recognized: (1) large solitary abscesses in muscles, (2) disseminated abscesses in muscles, and (3) diffuse purulent infiltration of the muscles. Most of the cases belong to the first group.

This young married woman, age twenty-two, the mother of one child, was entirely well until one month ago. At the time she retired feeling quite well and awoke after a short nap with a feeling that her legs had gone to sleep. She got out of bed without difficulty but while doing so noticed transient sharp pains in both knees. After walking about a little the posterior group of muscles of both the thighs seemed to go into spasm, and became quite sore. She went to bed again but when she awoke she found that both upper legs were quite painful, and she could not bend her knees. Her throat was quite sore and she had a temperature of 102° F. A physician made a diagnosis of rheumatism and prescribed treatment. After remaining in bed at home for ten days with no improvement, she was sent to the hospital. Efforts while there to remove pus by needle were unsuccessful. She remained in the hospital ten days and had a temperature of 100° to 103° F. every day. She showed some improvement and was sent home. However, the condition did not subside and she came to the clinic.

The past history, family history, inquiry by systems are essentially negative to the present illness.

The physical examination was essentially negative except that there was marked tenderness, indurative swelling and

hyperthermia over the posterior group of muscles of the left thigh. The muscles of the right thigh were tender and slightly swollen but to a lesser extent than the left.

The leukocyte count was 17,500, hemoglobin 70, red blood cell count 3,800,000. The urine is negative. Wassermann and Kahn tests are negative. Cultures from the throat showed *Streptococcus viridans*; those from the nose *Staphylococcus albus*. x-Rays of the thighs showed no bone or periosteal involvement. Aspiration about the middle of the posterior surface of the left thigh with a large needle produced about 50 cc. of thick yellow pus. Two large incisions were then made and 400 cc. of pus were obtained. Cultures of the pus showed a heavy growth of *Staphylococcus aureus*. No anaerobes were found.

The source of this infection is not definitely determined; its origin is most likely through the mucous membrane of the nose and throat.

**Dermatomyositis** is an acute or subacute inflammation of the muscles of unknown etiology associated with edema and dermatitis. It is characterized by a gradual onset with pain, rigidity and tenderness of the muscles, edema of the extremities, and a rash resembling one or another of the exudative erythemas. In addition there are general symptoms of malaise, anorexia, general debility and fever. As a general rule the inflammatory condition is not confined to the muscles, though acute pain and stiffness of the muscles with prostration, constitute a big part of the picture; inflammation in the skin, mucous membranes, nerves, spinal cord or serous membranes may be associated with the myositis to varying degrees. The skin over the affected muscles is edematous and the dermatitis takes various forms—erythematous, urticarial or erysipeloid. The skin lesions most often resemble erysipelas but differ from the latter in that reddening, though varying in degree, may last for weeks in the same place. When the mucous membranes are involved severe vomiting or diarrhea or both may occur, ceasing, however, long before the myositis does if the condition does not end fatally. When the serous membranes are involved peritonitis, pericarditis or pleurisy may occur.

The muscles become too painful to be used; the course is usually progressive, and after some weeks or months death may result from involvement of the muscles of deglutition or respiration, perhaps with bronchopneumonia. If the patient survives there are generally deformities from fibrotic fixation of the substance of the muscles leading to various contractures and deformities but these differ from the effects of rheumatic arthritis in that they are not especially related to the joints.

The disease must be distinguished from trichiniasis but in this disease the symptoms are first those of a pyrexial gastro-enteritis, these being followed by acute pains and aches all over the body, particularly the muscles. The muscles swell, the face and neck and trunk are affected as well as the limbs, the face and eyes become edematous, high fever is not rare and eosinophilia and leukocytosis are usual. Adult trichinella may be found in the stools and larval trichinella in portions of the affected muscle; encysted larvae may be found in the affected meat that gave rise to the attack should any of it have been preserved.

*Polymyositis haemorrhagica* is an acute, subacute or chronic disease, of unknown etiology, strongly resembling dermatomyositis but differing from it chiefly in the presence of interstitial hemorrhage between the muscles and occasionally by circulatory symptoms caused by impairment of the cardiac muscle. Purpura and hemorrhages from the mucous membranes may occur.

*Myositis ossificans* is the abnormal growth of bone in muscle or fascial planes. It occurs in two chief forms—localized myositis ossificans and progressive myositis ossificans. Local myositis ossificans may occur after repeated injuries or a single severe one.

This patient, aged sixteen, while playing football about three months ago was tackled hard, receiving the blow on the lateral side of the right thigh. The right thigh muscles became swollen and tender, and the patient could not bend the knee. The skin was not broken and no blue areas were noted. About a week later he noted a hard, firm mass on the anterolateral aspect

of the right thigh. The stiffness and tenderness persisted, and he came to the clinic.

Examination at that time revealed a diffuse, hard, firm mass on the lateral aspect of the right thigh. It was about 25 cm. long and about 3 cm. wide, and extended from just below the lesser trochanter to the junction of the middle and distal third of the thigh. x-Rays showed the bone mass as described. The CO<sub>2</sub> combining power was 65.3, serum pH 7.57, serum calcium 10.7 mg. The leg was put in a long leg cast which was bivalved, diathermy was given three times a week, a low calcium diet and large doses of ammonium chloride were prescribed. At the present time, two months from the first visit, the tenderness and pain have disappeared, the knee can be completely flexed, and the bony mass has decreased to about one third its former size.

**Localized myositis ossificans** is occasionally seen in the adductor longus (rider's bone) following bruising or partial rupture of the muscles, occurring especially in cavalry soldiers, and in the deltoid and pectoral muscles of soldiers (drill bone) from bruising by the rifle in drill. The diagnosis has to be made from hematoma, new growths and exostoses. The history and x-ray study are important in differentiating these conditions. Local myositis ossificans reaches its maximum size rapidly, and usually diminishes slowly.

The **progressive form of myositis ossificans** is an irregular, generalized, progressive ossification in or adjacent to the voluntary muscles. Because of the hardening process in the neighborhood of the joints ankylosis usually supervenes. The cause of the disease is unknown. The antecedent factors are usually injury, excessive muscular strain or chronic disease of the joints. Microdactylia or valgus deformity of the great toe and thumb occur in 75 per cent of the cases. The process usually begins in the neck or back with swelling of the affected muscles, redness of the skin and slight fever. The later subsidence of the process is not complete, induration persists, followed by fibrosis, and this then becomes the seat of bony deposits, growing progressively harder as the process

continues. The disease involves chiefly the muscles of the trunk, upper extremities and neck, trapezius, latissimus dorsi, sternocleidomastoids and shoulder muscles. Death usually results within a few years from intercurrent disease such as bronchopneumonia or from involvement of the masseter muscles and starvation.

**Treatment.**—The treatment of primary suppurative myositis is mainly surgical, and depends for its success on early recognition. Before localization occurs hot boric acid application may hasten the process. The treatment of dermatomyositis and polymyositis haemorrhagica is very unsatisfactory. Until some further progress is made in the knowledge of the infection and immunity to the disease, one cannot reasonably expect specific therapy. Rest in bed, baths, fomentations and massage will ameliorate the symptoms, and probably modify the stiffness and tenderness which are so annoying. Various analgesics have been tried, including the salicylates, but no particular drug has been found to offer any special advantage. It is important to keep up the patient's nutrition by an adequate diet. Fortunately these conditions are rare.

The most important therapeutic measures in local myositis ossificans are: (1) rest, (2) immobilization when possible, (3) diathermy, (4) elimination of foci of infection, (5) a low calcium diet, (6) relatively large doses of ammonium chloride may be tried. Surgical excision may be indicated in some cases. The medical treatment of the progressive form of myositis ossificans avails very little. The removal of the bony masses has been done with unsatisfactory results as there is usually a recurrence at the site of removal in almost every instance. By exercising precautions against trauma, and by the use of the therapeutic measures indicated in the localized form of the disease, the affection can occasionally be prevented or at least delayed from spreading.

### RECOGNITION AND MANAGEMENT OF DEFENSIVE AND WORRY NEUROSES

**Case I.**—The first patient I wish to present today is M. M., a white married woman of fifty-five. She complains of numbness of the hands, occipital headache, insomnia, urinary frequency, and constant burning and itching of the vulva and anus. She states that she has been "nervous" for thirty-one years and that during the past three years her present symptoms have become progressively worse. The past surgical history is of interest. She was married at the age of twenty. Three years later she had an operation on the cervix uteri and after another five years she had a suspension of a retroverted uterus. Twelve years after her marriage the right ovary was removed because of a dermoid cyst. The following year this patient had an appendectomy for chronic appendicitis. Two years later she had a tonsillectomy and in the same year a supravaginal hysterectomy. Recently a proctologist reported perianal kraurotic changes as the cause of her pruritus and advised surgery, but the patient refused to submit to this operation. The general medical examination was within normal limits. The neurological examination was negative and no objective sensory disturbances were demonstrable.

The patient was born in Sicily and is the oldest child in a family of six. The father was a railroad laborer who was rarely at home. He died at sixty of a urinary tract infection. The mother is alive at seventy-six, and has long been an invalid

because of "neuritis." As a little girl the patient was a "tomboy," physically a match for her younger brothers. During her father's long absences she was always eager to help her mother with the heavy work, but had no interest in sewing and cooking. When the patient was nine the father went to the United States, and two years later she came here with her mother and the younger children.

The first menstrual period occurred when the patient was fourteen. She was very alarmed and feared that she had injured herself in some of her tomboy activities. She could not bring herself to tell her mother, and when the truth was discovered the mother gave her a minimum of information and did not reassure her. From that time on the patient states that she had severe cramps during each period which forced her to go to bed. The patient subsequently gave up all "tomboy" activities and spent her time helping her mother do piece work sewing at home. She had little in the way of social life and out of deference to her mother's wishes married an Italian five years her senior when she was twenty years old. Her sex life began with dyspareunia and vaginismus and continued with complete anesthesia. She has never been pregnant.

At the time of her marriage the patient's husband was employed in a restaurant. Within a few years he became the proprietor and the business prospered. During these years the patient remained at home a nervous housewife, with no social interests or outside activity, except as a patient in various surgical wards. After forty years in this country her English is still very poor. During the late 1920's the husband's business expanded, and in 1933 he lost everything. He reacted to this failure with a depression and for two years was on relief. At present he has a position as a private policeman, but apparently has not the courage to make a "come back."

Since the husband's failure the patient's condition has become much worse. She showed no inclination to find employment outside her home or to aid her husband in any practical way.

The psychological treatment in this case was begun with a

study of the patient's dreams, several of which were sufficiently clear to be worth repeating. The first dream consisted of a group of women, including the patient, admiring a young woman who was nude to the waist and had no breasts. Another dream was of the patient trying to drive a small automobile up a mountain road. The mother who was beside her became so anxious that it was necessary to abandon the attempt and back the car down the hill. These dreams contain the two main features of her neurotic conflict—the admiration of the masculine woman and the fact that she had been forced to renounce this ambition.

The patient has been able to accept these facts, but has not the courage to attempt a more masculine adjustment at the age of fifty-five. In the light of her present inability to adopt a more aggressive rôle the exacerbation of her symptoms at the time of her husband's failure becomes understandable, as this presented a challenge to this dormant side of her personality. The pruritus and the paresthesias of the hands are probably related to an early masturbatory conflict, but as is frequently the case in older women, this view could not be confirmed. From a therapeutic standpoint, little is to be expected beyond some amelioration of her more distressing symptoms.

The chief interest in this case is the surgical history. She is a type of woman who is unable to accept the feminine rôle without conflict. She had dysmenorrhea and dyspareunia, and never became pregnant. Anatomically she had a retroverted uterus and later developed an ovarian dermoid. Without presuming to express an opinion as to whether the physiological and anatomical findings are the cause or the effect of the psychological syndrome, it is of interest how frequently this psychophysical parallel is encountered. From the surgeon's viewpoint it is well to remember that a patient who seems to require a series of operations on the pelvic viscera, or any other organs for that matter, may be expressing an unconscious need to injure the organs in question. In the case of this patient if a plastic could have changed her sex, no doubt a single operation would have been successful.

**Case II.**—Our second patient today is R. A., a white male of twenty-nine, who complains of attacks of palpitation, vertigo, sweating, trembling, during which he feels like a cornered rat. The patient must escape at any cost. The past medical history reveals bronchial asthma as a child and lobar pneumonia in adult life. Neurological examination is entirely normal. There is a static tremor of the extended hands which are cold and sweating and a pronounced sinus arrhythmia.

The patient is an only child. His father is sixty-two, and a successful physician. His mother is fifty and in good health. Apparently their marriage has been unhappy. The mother is a domineering type who is athletic, a bridge expert, and a leader in women's organizations. There is something masculine about her appearance, and she wears the pince-nez glasses of a successful woman executive. She has never been able to adjust to the sexual side of marriage and has been unwilling to bear another child.

When the patient was a small boy he had severe bronchial asthma. During the northern winters, his mother would take him South for several months, leaving his father in Illinois. Each year these winter vacations became longer until finally the father moved to Florida where the family made a permanent residence.

Throughout his childhood the patient shared a bedroom with his mother and the father had separate quarters. The father was completely engrossed in the practice of medicine and his relaxation at home was usually *solitaire*. The mother always nagged him about the way he snapped the cards as he laid them out and criticized his table manners and dress. Apparently he was oblivious to her remarks.

The patient was treated very indulgently by the mother. However, she insisted on his maintaining a creditable standing at school. He always found his studies easy but was usually so apprehensive in examinations that he never did himself justice. Finally at college during an examination he became so tense that there was a spontaneous orgasm. After this, his examination fears became so severe that he failed in his first

year at medical school. This failure filled him with remorse. He deliberately exposed himself to the cold weather insufficiently clad and subsequently developed a lobar pneumonia during which he wished to die. After his recovery he returned to the family home and made no further attempt to continue his medical education or find other employment.

The sexual education of the patient was another point at which he was confronted by maternal discipline. Although he shared a bedroom with his mother until he went to college he was supposed to possess no sex information. During his teens he was frequently accused by her of masturbation and his sheets were always examined for any evidence of nocturnal emissions. The patient denies any overt sexual behavior until his senior year at college when he had an affair with a girl who was his social inferior. This was terminated by the mother who paid the bill for an abortion.

About one year ago the patient became infatuated with another woman ten years his senior whom he realized he could never marry because of the difference in their religions. He states that their sexual relations, although frequently perverse in character, were mutually satisfactory. However, he frequently experienced an overpowering desire to escape from her. When his mother realized the depth of this attachment she advised him to give up this woman and to frequent prostitutes. She made the definite statement that he could never marry because it was his duty to live with her after the death of his father. When the patient could not be persuaded to terminate the affair, he was referred to a local psychiatrist who advised sending him away.

The mother found the patient a position in Chicago as a salesman and arranged with his employer that he be paid a salary whether he was able to sell or not. A maternal aunt provided a home for him. Psychological treatment was undertaken at this time.

The patient proved to be very cooperative and intelligent. After several weeks of psychotherapy he began to develop an interest in his emotional dependence on his mother and also

his antagonism to her. He also came to the realization that the second woman was a mother substitute. His panic attacks disappeared, and he surprised his family by actually making a success of selling. He made various social contacts and new friends.

At this point the mother came here from Florida. As soon as she sensed that the patient's attitude of dependence was being broken she insisted that her son discontinue the treatment and return to his home. As might be expected he has agreed to comply with her wishes.

This case has been presented to illustrate the importance of the home environment in the etiology and continuance of a psychoneurosis. It has not been attempted to deny that there was probably some constitutional factor which made this patient likely to develop a psychoneurotic reaction. However, the history plainly demonstrates that the mother's inability to solve her marital and maternal relationships was an important factor in the patient's emotional attitudes. When one speaks of hereditary factors in psychoneurotics, it is frequently a situation of this kind which is meant. In this sense the "sins of the fathers may be visited upon the children even unto the third and fourth generations."

**Case III.**—The next patient I wish to present is L. N., a white married woman of forty-two. She complains of pains in her lumbar spine radiating up to the neck, occiput and both her eyes. The pain began six months ago when she had a pyelitis after a miscarriage. She had the ureter dilated and was told she had a fallen kidney. When the pain persisted a tonsillectomy was performed. Osteopathic treatments for a "displaced vertebra" were without benefit. Thorough examination by an eminent internist revealed minimal osteo-arthritis of the spine, slight obesity, and two infected teeth. Neurological examination is within normal limits. The past medical history is unimportant.

The patient's father is a retired clergyman of seventy-five who has a carcinoma of the stomach. Her mother died of

myocarditis at fifty-seven. The patient has two older sisters, one married, and one a school teacher. A brother died at twenty of pulmonary tuberculosis. There is no family history of nervous or mental disease. Ten years ago the father married a widow of fifty. This was against the wishes of the patient who is still unreconciled to her stepmother.

The patient states that as a child she resented the fact that the father's income was inadequate and the mother was always overworked. She had many plans to improve the situation. She did well in school, took a business course, and got a good position at eighteen. She continued to live at home and gave her salary to her mother. She married at twenty-four, rather impulsively, a soldier who was preparing to leave for France. After two weeks of married life he sailed and was subsequently killed in action. The patient was not particularly disturbed by this. She states that the sexual side of marriage meant nothing to her, although she wanted to have a child.

After the death of her husband she continued to hold a good position and to live at home. She became interested in various charities and finally started to give night courses in English to immigrants. One of her pupils was an intelligent Swedish inventor who was utterly impractical and unable to earn a comfortable living. Nine years ago she married this man but insisted that her unmarried sister share their home. (This marriage was probably related to the second marriage of her father a year before, which was previously mentioned.)

After the second marriage the patient made a fair adjustment as a housewife. She and her sister invested their savings in the husband's inventions which always turned out to be disappointing. The only difficulty in this household was constant friction between the sister and the husband, especially over money matters. About a year ago the patient became pregnant for the first time. The husband was enthusiastic about the prospect of a child, but the sister was most unkind stating that the patient was too old for child-bearing. At about five months the patient had a miscarriage without apparent cause. This was followed by a pyelitis and pain in the back. About this

time the patient developed a compulsive desire to lift a heavy buffet in her dining room. This would aggravate her backache. In spite of the pain she would experience an overpowering temptation to lift the buffet and would finally yield until this became a daily ritual.

The treatment of this patient from the psychologic side began with a study of her compulsive lifting. It was obvious that she was deliberately attempting to aggravate her backache and her nervous condition. Her purpose in doing this was to worry her husband. She soon began to express her hostility to him quite openly, keeping him awake most of the night with interminable discussions about lifting the furniture, vomiting if he was late to dinner, threatening to make home so unpleasant that he would have to leave her, and harping on his economic inadequacy. Conscious death wishes against him were also present. The patient reacted to these with remorse and began to make threats of suicide which, however, were never attempted. She was mildly depressed at this time. Finally she began to understand that her hostility to her husband was merely another instance of her lifelong reluctance to make a feminine adjustment. Her compulsive lifting disappeared and she insisted that her sister move away. She is now attempting to develop a more normal attitude to her marriage with its economic insecurity and childlessness. Her backache is still present but is less severe and recently she has been benefited by massage and physiotherapy.

This case has been presented to demonstrate the inadequacy of the physical viewpoint in treating a backache. We have a history of an acute infection before the onset of the pain, x-ray evidence of osteo-arthritis of the spine, and a chronic dental infection. However the most important feature in this case was a compulsion to lift heavy furniture with the intention of aggravating the pain. When the motives behind this apparently irrational behavior were understood it became possible for this patient to attempt to work out a better solution of her emotional difficulties. As this adjustment becomes more successful the psychological need for her pain will continue to diminish.

Before concluding this clinic a few general remarks about psychoneurotic reactions might not be amiss. The various contemporary schools of psychiatric thought may disagree on therapy or on the importance of heredity, infection or other physical factors in the etiology of the psychoneuroses, but the opinion is becoming increasingly accepted that a psychoneurosis can be understood only psychologically. Consequently the time-honored method of diagnosing a psychoneurosis by excluding organic disease is no longer valid. A patient with panic attacks like the second case presented today has a characteristic history which is just as typical as the history of duodenal ulcer and with which all physicians should be familiar. The rational treatment of the psychoneurosis is some type of psychotherapy and should be instituted promptly, not years after ill-advised and unsuccessful surgery, as in the first case presented today. There is no reason why the general practitioner should be unable to undertake minor psychotherapy with the same confidence with which he does minor surgery. Success in either requires only a frank realization of his limitations as a therapist and a willingness to ask for assistance in his more difficult cases.

### THE CHICAGO MEMORIAL HOSPITAL

---

#### CLINICAL APPLICATION OF RENAL FUNCTION TESTS

DIAGNOSIS by merely giving a disease a name does not suffice. There are many forms of Bright's disease, differing widely in etiology, symptoms, progressiveness, prognosis and in the character and extent of depression of functions. Comprehensive diagnosis should include consideration of the probable *etiology*, the *pathologic lesions* and the type and degree of *functional impairment*. In renal disease, etiology and the functional status of the kidneys are the more important considerations. Curative therapy frequently depends upon recognition and correction of etiologic factors. It is wholly impossible to judge the severity of renal injury on either the intensity or duration of such common symptoms as albuminuria, edema, casts, and arterial hypertension alone. Many of these phenomena may be due largely to extrarenal factors; this is certainly true of edema and/or hypertension. Diagnosis, especially in chronic disorders, should include quantitative impressions as well as qualitative.

Functional studies are, therefore, necessary for proper diagnosis in renal disease. It is characteristic of all normal living structures to have a wide margin of safety or functional reserve. The existence of such reserve is most conspicuously manifest clinically in the heart, for we can readily observe the phenomena of increased cardiac effort when the circulation is placed in a state of stress. *Symptoms* of failure do not appear unless the functional demand is actually greater than the functional capacity. Thus, for example, in heart disease, functional evaluation depends not upon the phenomenon of dyspnea, but

upon the *degree of effort* necessary to induce dyspnea. In frank cardiac decompensation dyspnea appears without added effort; the labor of mere existence is greater than the functional capacity. A similar, but less readily dramatized, situation exists in the problem of renal functional capacity. There are no pathognomonic symptomatic evidences of renal functional impairment *until* the functional burden exceeds the functional capacity, or, in other words, until the functional *reserve* has been depleted to the point of renal decompensation. At such a point, resulting in the state commonly called "uremia," functional studies become largely unnecessary; the functional failure is then conspicuous. But before this occurs there is usually a long period of *impaired reserve*, the detection of which depends upon renal function studies. We start life with a renal margin of safety of about 400 per cent; the normal young animal can maintain health with one-half of one normal kidney. Inevitably, through transient infections and the multitude of insults from the vicissitudes of existence, this margin is gradually depleted. Such depletion is, of course, tremendously accelerated by actual renal disease; acute nephritis may quickly reduce the functional reserve to below normal requirements, although renal decompensation or uremia occurs more commonly after years of chronic nephritis.

The objectives of renal function study in clinical practice are both qualitative and quantitative. Such study may be applied to determine whether or not functional injury exists. as, for example, in orthostatic albuminuria, where, despite the profuse proteinuria, the renal functions are essentially normal. Following a febrile albuminuria it is wise to determine the renal functional reserve by appropriate tests to insure against diagnostic error and avoid missing a latent nephritis. In acute nephritis function studies are especially indicated after the subsidence of acute phenomena; it is necessary to have a base line for future comparison in order to measure progress—progress in either direction. In such instances, as in chronic nephritis, it is best to repeat such studies at intervals.

In hypertensive arterial disease<sup>1</sup> renal function studies are

of the greatest importance. Etiologic correlation between nephritis and hypertensive disease may occur in three ways: (1) renal impairment may cause hypertension; (2) hypertensive disease may impair the renal function through malcirculation (nephrosclerosis), and (3) both the arterioles and renal parenchyma may be injured simultaneously. Where hypertension is not due to nephritis, and this group includes the great majority of cases of hypertension,<sup>2</sup> repeated determination of the renal functional reserve makes possible observation of the progressiveness of nephrosclerotic changes.

Another field of usefulness for clinical renal function tests is in genito-urinary diseases where the problem of renal efficiency is often of paramount moment. Lastly, but by no means of least significance, renal function studies are often urgently indicated in the care of pregnant women. Prenatal application of such studies serves to detect latent or "silent" renal damage from early infections and/or previous pregnancies and thus forewarn of difficulties. In the "toxemias of pregnancy" renal function tests will frequently distinguish between preexistent nephritis and late renal fatigue. As the prognosis and therapeutic management of the various types of nephritis in pregnancy differ widely, it is of great importance accurately to differentiate the types.<sup>3</sup> Too many instances of preexistent nephritis go undetected in obstetric practice and, as a result, the exacerbations induced by pregnancy do extensive, irreparable harm. Whenever there is reason to suspect the possibility of previous renal injury from the history of the patient, preconceptional study of the renal functions is indicated. It has come to pass that young women with known heart disease frequently consult a physician for advice and prognostic information before marrying or before risking pregnancy. It is unfortunate that the opportunity for similar preconceptional evaluation of the renal reserve is not more frequent. The fact that the burden of renal reserve is inevitably and considerably increased during many weeks in pregnancy must not be forgotten; the functional *reserve* thus assumes particular significance prior to such predictable stress.

## PHYSIOLOGIC ASPECTS OF THE RENAL FUNCTION TESTS

The functions of the kidneys may be conveniently divided into four major activities: (1) elimination of waste water (solvent); (2) elimination of waste (metabolic) solutes, which include both electrolytic salts and the organic *débris* of metabolism; (3) elimination of substances foreign to the body and especially those foreign to the blood stream (such foreign substances may or may not be noxious), and (4) aid in maintaining the acid-base equilibrium of the body.

Certain of these functional activities are open to clinical investigation. One may measure the renal response to a demand to secrete water quickly (the solvent), the ability of the kidneys to concentrate the urine (secretion of solutes), the effectiveness with which certain substances, such as urea, are cleared from the blood stream, and, with appropriate materials, study the excretion of foreign substances. Failure of the kidneys to maintain a normal acid-base balance is detectable, but, as yet, we have no satisfactory clinical test for measuring the *reserve* power of the kidney to cope with such disturbed equilibrium.

Physiologic evidence indicates that the greatest part of the renal work is expended in concentrating the urine. It is probably more work for the kidneys to excrete a small volume of highly concentrated urine than a large volume of dilute urine. As all procedures intended to determine *reserve* depend on the response to increased effort, this fact becomes of great significance in evaluating the various function tests. To detect hidden weakness or weakened reserve, it is necessary to create conditions of stress, for under the normal load the structure may be perfectly competent. The tests involving stress are thus the most sensitive to early or minor damage. This is true both theoretically and in actual clinical application, although the "stress tests" are not necessarily also the most satisfactory for accurately determining variations in the renal functional capacity when *extensive* injury exists.

Almost innumerable test procedures have been suggested at one time or another. Many of these have been found want-

ing. We shall limit ourselves to three or four procedures of proved merit, each with relatively specific indications, and discuss their significance and limitations. The essential criteria of a practical clinical function test are: (1) physiologic soundness; (2) specificity for the functions or structures studied; (3) safety; (4) simplicity; (5) relatively uniform normal response, and (6) sensitivity sufficient to reveal impairment not too far removed from the borderline of normal. Because elaborate laboratory facilities are not always available, simplicity is necessary if the procedure is to serve the largest number of patients possible.

### TESTS

Concentration of the urine requires a major fraction of renal effort. The response of the kidneys in concentrating the urine under conditions of stress is unquestionably the most sensitive test for early depletion of reserve function. To force the kidneys to secrete a highly concentrated urine, if possible, is the equivalent of asking the renal parenchyma "to climb a hill" and thus weaknesses are brought to light. Such stress conditions obviously can be induced in either one of two ways: (1) by the addition of solute, and (2) by the withdrawal of solvent (urates).

The first of these methods is illustrated by the **urea concentration test**, introduced by Maclean and de Wesselow.<sup>4</sup> The procedure is as follows:

After eighteen to twenty-four hours with a small intake of fluid and at least three hours after food, the patient voids and immediately thereafter takes by mouth 15 Gm urea dissolved in 100 cc. of water. Urine specimens are obtained *one and two hours* after the administration of the urea. These are examined quantitatively for their urea content. During this two-hour interval the patient takes no food or drink.

If *either* specimen contains urea in excess of 2 per cent the renal function is considered normal. The higher the *concentration*, the greater is the renal functional reserve. Diuresis, of course, will cause dilution and, therefore, the test is deemed satisfactory only if not more than 120 cc. urine are secreted in

the second hour. Urea itself may cause considerable diuresis in the first hourly interval. This test has proved to be very valuable, is sensitive, safe and involves only two urea determinations on the urine. It is definitely a "stress test" and reveals early impairment.

Similar conditions of stress may be induced without the introduction of anything into the patient, by depriving the body of water for a stated period. This concept has been the basis for many test routines which differ slightly in detail but have the same basic principles. Perhaps the simplest and most satisfactory routine is that of Fishberg.<sup>5</sup> The technic for his **renal concentration test**, as carried out in this clinic, is:

The patient receives no fluids or food after the usual supper until the test is completed. At 7 A. M. the patient voids and this specimen is discarded (this urine was secreted during the night). At 8 A. M., 9 A. M., and 10 A. M., respectively, separate specimens of urine are collected and marked with the hour of voiding. The object of the test is to obtain specimens of urine as concentrated as possible after the body has been deprived of water for fourteen to sixteen hours. It is not essential that the urine be voided exactly on the hour as long as the collections fall within the period of 8 to 11 A. M.

The specific gravity of these specimens is then determined, and the highest specific gravity taken as a measure of the concentrating capacity of the kidneys. Normally, at least one specimen reveals a specific gravity of 1.025 or higher; the normal range is from 1.026 to 1.034 under these standardized conditions of relative dehydration. Failure of the kidneys to concentrate the urine above a specific gravity of 1.020 is indication of definite impairment of functional reserve. The lower the maximum specific gravity, the poorer is the renal functional capacity. In renal decompensation the maximum concentration is often about 1.010.

There are several sources of error which deserve mention. Most important and frequent of these is the error introduced when diuresis occurs from water stored in the tissues; the test is valueless and misleading if carried out during the subsidence of edema. With edematous patients, therefore, great caution must be observed in interpreting results which show low urinary

concentration. The occurrence of edema loss can be confirmed by observation of changes in body weight and/or by repetition of the test under better conditions. Accurate measurement of the specific gravity with calibrated equipment is essential. An obvious, but often ignored, error is introduced by failure to have the urine at 21° C. when the specific gravity is measured; almost all hydrometers are calibrated at this temperature. Determinations made on freshly voided (warm) urine and/or urine from the refrigerator are absolutely worthless. Very large amounts of protein in the urine raise the observed specific gravity and thus mislead, for the protein is not a true secretory solute. The specific gravity is increased 0.003 by 1 per cent dissolved protein or 1000 mg. albumin per 100 cc. of urine.<sup>6</sup> Such severe albuminuria is observed but very exceptionally. Small amounts of protein do not affect the results appreciably.

This is the simplest of the renal function tests. It is readily carried out with a minimum of equipment, requiring chiefly only intelligent observation and interpretation. It can be a routine office procedure with proper instruction of patients; I believe it should become one. It is obviously wholly devoid of risk to the patient. But it is commendable primarily because: (1) it is thoroughly physiologic in principle, and (2) it is *the most sensitive test in detecting minor degrees of reduction of the renal function*.<sup>1, 3, 7, 8</sup>

Of the many other related procedures, that suggested by Mosenthal<sup>9</sup> is the best known and most useful. By administering known volumes of fluid at specific hours and obtaining urine at intervals of two hours during the day, it is possible to gauge not only the ability of the kidneys to concentrate the urine, but also the promptness with which ingested water is eliminated. This **concentration-dilution test**, however, yields but little more useful information than the simpler procedure just discussed.

The advent of accurate methods for the quantitative chemical analysis of blood produced a towering wave of enthusiasm for "blood chemistry" as a means of diagnosis. More recent microscopic methods, which require but a few drops of blood,

have further accelerated clinical studies. We are deeply indebted to the chemist for these methods, but we must not be misled by blind faith in laboratory data just because they are derived by methods of precision. No matter how accurate the analytical method, the significance of the data depends upon our understanding of the *physiologic* variables. In human biology these are legion. I do not want to belittle the value of blood chemical analysis; in many instances such studies reveal the basic disturbances responsible for obscure phenomena. The hypoproteinuria of nephrotic edema, discovered by such clinical studies of the blood, is an example. In connection with renal function tests, however, one must remember that notable increases in the concentrations of urea, uric acid, creatinine, nonprotein nitrogen, etc., occur only with renal failure. Mild hyperazotemia may result from metabolic disturbances and shifts in water balance without renal failure. Thus minor fluctuations in concentration are difficult of interpretation. In "compensated" nephritis the "blood chemistry" fails to measure the *reduced reserve*.

As urea retention is characteristic of renal failure leading to clinical uremia, special emphasis has been placed on the study of urea excretion. Multiple attacks on this problem over more than twenty years have gradually evolved the urea clearance test. By "blood urea clearance" is meant the number of cubic centimeters of blood cleared of urea by renal secretion per minute. The formula for expressing this is  $\frac{UV}{B}$ , where U is the concentration of urea in the urine, V the volume of urine in cubic centimeters per minute, and B the concentration of urea in the blood. When the volume of urine is less than 2 cc. per minute the urea secretion is depressed by the square of the reduction in volume and thus, when less than 120 cc. are excreted per hour, the formula must read  $\frac{U}{B} \sqrt{V}$ . This latter is termed "standard" clearance, the former "maximum" clearance. The average standard normal clearance is 54 cc. blood cleared per minute, the average normal maximum clearance is 75 cc. blood per minute.

Careful studies<sup>10</sup> reveal that the urea clearance is a very accurate guide to the effectiveness of glomerular function. In severe nephritis this test gives clear evidence of change for the better or worse. In milder instances the test is not so sensitive in revealing lowered reserve as the concentration test.<sup>1, 7</sup> It is not a "stress test" as carried out at present. It is physiologically sound and not so complex as appears at first thought. A sample of blood is drawn immediately after the patient voids and then one hour later the specimen of urine is collected.

Innumerable substances have been introduced for use in measuring renal excretory efficiency, but thus far **phenolsulphonphthalein** has proved most satisfactory. This nontoxic dye is extraordinarily specific for kidney tissue; 98 per cent of injected dye can be reclaimed from the urine and kidneys of dogs.<sup>11</sup> The dye is secreted largely by the proximal convoluted tubules. The procedure for the test varies in different clinics, chiefly in the time interval at which specimens are collected. Here the routine is to collect urine specimens one, two and three hours after the intravenous injection of exactly 1 cc. of the dye solution (ampule). Some advocate shorter time intervals, but then it is often necessary to catheterize the patients and this is best avoided. The amount of dye excreted is determined colorimetrically in an alkaline dilution of the urine.

The "phthalein" test has deserved popularity. It is not, however, as sensitive to minor changes in function as the concentration test. The promptness of secretion is important. It is particularly adaptable to unilateral investigation of the kidney function; with ureteral catheters in place it is possible to determine the dye output on each side separately. Two readings at fifteen-minute intervals suffice. In rare instances some metabolic quirk causes chemical destruction of the dye within the body. If the urine contains no dye after injection, this is thus no proof of renal failure. With coincident hepatic disease the urinary output of the dye is increased. All these and other variables must be considered in interpreting the results of this test.

Very recently a new test substance has received clinical

trial. Sodium ferrocyanide is secreted solely through the glomeruli.<sup>12</sup> This test procedure is still in an experimental stage,<sup>13</sup> but various studies show a close parallelism between the ferrocyanide excretion and the urea clearance.<sup>14</sup>

As stated before, we have no adequate method for detecting early depression of the renal activities in maintaining the acid-base balance of the body. Gross shifts toward acidosis or alkalosis are measurable by determining the CO<sub>2</sub> combining power of the blood (van Slyke). An intensive clinical study of this aspect of the problems of nephritis is needed.

#### CLINICAL APPLICATION OF TESTS

There are so many clinical applications for renal function studies that it is impossible to do justice to the subject here. Some of the indications we have mentioned previously. Four clinical examples may serve to illustrate certain points of interest.

**Case I.**—The first patient, Miss E. H., is a girl of fifteen years, who was first admitted to the hospital about a year ago. The primary complaints were habitual exhaustion and undernutrition. Vertigo, recurrent headache, increasing asthenia followed a coryza with cough two months prior to admission. The cough persisted. She denied previous illness. Her menses started at thirteen, but had been increasingly scant the last six months. The intern suspected tuberculosis because of her marked undernutrition and the persistence of some cough. Examination revealed a tall, very thin, pale girl appearing much more mature than her age. Her physique was typically Stiller in type. The chest was resonant throughout, with a few fine crepitant râles scattered diffusely through the pulmonary fields. These râles did not persist after intentional coughing. The heart was not enlarged and no murmurs were heard, but the second aortic sound was accentuated and ringing in character. The intern had not determined her arterial tension "because she was still a child." Her blood pressure was found to be 150/100. Specific inquiry revealed that she had been ill for

four months with a very severe attack of scarlet fever three years previously. You will recall that the girl had told the intern she had had no previous illness. This misstatement was not deliberate or with intent to mislead; she had merely not associated "previous illness" with her scarlet fever. To get an accurate story it is necessary to be specific in questioning.

Urinalysis revealed 40 mg. albumin per 100 cc. urine, granular casts and some erythroplastids. The x-ray film of the chest was normal. Anemia was marked: hemoglobin 68 per cent (Newcomer), red blood cells 3,140,000, white blood cells 8550. The diagnoses were:

1. Chronic nephritis (postscarlet fever).
2. Early, spastic hypertensive arterial disease.
3. Anemia, secondary.
4. Undernutrition.
5. Recent coryza precipitated symptoms.

These, however, were purely qualitative diagnostic impressions. Further study was needed to reveal the extent of renal function impairment. The following data were elicited:

1. Renal concentration test:

Maximum specific gravity = 1.021

(repeated) specific gravity = 1.020

2. Phenolsulphonphthalein excretion:

60 minutes 60 per cent

120 minutes 20 per cent

Total 80 per cent

3. Urea clearance (standard): 56 cc. blood cleared per minute.

4. Glomerular function test (sodium ferrocyanide):

30 minims	9.3 per cent	Normal = 12 to 17 per cent
60 minims	7.9 per cent	8 to 12 per cent

Total	17.2 per cent	20 to 30 per cent
-------	---------------	-------------------

The function tests revealed: (1) impaired renal reserve (lowered maximum concentration); (2) normal "phthalein" output and urea clearance; (3) reduced glomerular function.

We cannot discuss therapy here, but, with this girl, the

most urgent indication was to correct the severe anemia. It is unjustified to expect rehabilitation and repair of tissues receiving an inadequate blood supply. Since then the patient has reported a number of times for re-evaluation of the situation. The thoracic findings cleared up promptly. Six months ago the following data were obtained:

1. Hemoglobin 76 per cent (Newcomer), red blood cells 4,180,000.

2. Arterial tension 124/84.

3. Renal concentration test:

Maximum specific gravity = 1.023.

4. Urea clearance (standard): 59 cc. blood cleared per minute.

5. Glomerular function (sodium ferrocyanide) output:

30 minims 14.3 per cent

60 minims 14.3 per cent

Total 28.6 per cent

The present findings are:

1. Hemoglobin 92 per cent (Newcomer), red blood cells 5,260,000.

2. Arterial tension 122/74.

3. Renal concentration test:

Maximum specific gravity = 1.024.

4. Urea clearance (standard): 58 cc. blood cleared per minute.

5. Glomerular function (sodium ferrocyanide output) continues normal.

The renal function tests on this case served not only to confirm and prove the original diagnosis and show that depletion of the functional reserve was as yet small, but also made possible proof that the renal function has returned to normal in the last year with correction of the anemia. It is interesting to note that the arterial tension also returned to normal with the improvement of the blood picture.

**Case II.**—The second case presents a somewhat different problem. A business executive of fifty-eight years has known

of his hypertension for fifteen years; it was discovered shortly after a severe streptococcal sore throat. At that time hematuria was marked. At present the chief complaint is that of typical anginal thoracic pain on either exertion or excitement. This has been getting worse. Hypertension has been responsible for three deaths in his family. The electrocardiogram reveals left ventricular preponderance and myocardial damage. His arterial tension is 220/120. Upon inhalation of amyl nitrite the arterial tension falls to a minimum of 130/80<sup>1, 15</sup> revealing that the arteriolar narrowing is largely spastic rather than arteriosclerotic. The urine contained many casts and 15 mg. albumin per 100 cc. The diagnosis included:

1. Hypertensive arterial disease.
2. Angina pectoris.
3. Oral sepsis.
4. Nephritis, degree undetermined.

Renal function tests revealed:

1. Renal concentration test:

Maximum specific gravity = 1.024.

2. Phenolsulphonphthalein excretion:

60 minims	50 per cent
120 minims	17.5 per cent
Total	<u>67.5 per cent</u>

3. Urea clearance (maximum): 71 cc. blood cleared per minute.

4. Glomerular function (sodium ferrocyanide excretion):

30 minims	12.8 per cent
60 minims	20.3 per cent
Total	<u>33.1 per cent</u>

These data demonstrate that despite the suggestive history of a streptococcal infection followed by hematuria and severe hypertension, the renal function is essentially normal. Renal impairment, therefore, is not an etiologic factor in this instance of hypertensive arterial disease. The patient should be treated as a cardiac problem, not renal.<sup>1</sup>

**Case III.**—This third case, W. J., was a young man of twenty-two years, who entered the hospital for renal function study. He was known to have nephritis. This dated from scarlet fever at five years of age. He had felt well until three months before admission. He complained bitterly of persistent headache, nausea, vomiting, dyspnea and cough. He was pale and very breathless. The significant findings were:

1. Hemoglobin 48 per cent (Newcomer), red blood cells 2,690,000, white blood cells 9,750.

2. Arterial tension 196/130.

3. Renal concentration test:

Maximum specific gravity = 1.011.

4. Urea clearance (maximum): 4 cc. blood cleared per minute.

5. Phenolsulphonphthalein excretion:

60 minims           — 5 per cent

120 minims         — 5 per cent

Total                ± 8 per cent

6. Glomerular function test (sodium ferrocyanide): only trace recovered.

7. Blood chemistry: nonprotein nitrogen, 184; urea nitrogen, 60; creatinine, 8.7; CO<sub>2</sub> combining power, 33.6 volumes per cent.

Such findings are typical of uremia. The fundamental failure lies in the inability of the kidneys to concentrate the urine. Despite the dehydration due to his vomiting (more severe dehydration than in the ordinary test) the maximum concentration was but 1.011. The prognosis was black; the hyperazotemia, profound anemia and acidosis reveal that the end was not far off. His parents were informed that his life expectancy was but four to eight weeks; no therapy could restore his lost renal function. He died at home six weeks later.

**Case IV.**—This last case example is perhaps the most instructive of all. When Mrs. A. S., twenty-six years old, reported for her first examination to the prenatal clinic she was

six months advanced in her second pregnancy. There had been, unfortunately, no previous prenatal care. She presented no complaints but her urine contained 60 mg. albumin per 100 cc. and her arterial tension was 160/100. No edema was demonstrated. She stated that her first pregnancy terminated prematurely with a rapid, violent labor and delivery of a stillborn infant. As the first pregnancy and delivery was without medical attention, our information depended entirely upon her statements. She denied ever having had scarlet fever, diphtheria, or rheumatic fever, but admitted a severe and prolonged sore throat eight years ago.

The problem presented was one of differentiating the possible reasons for this patient's hypertension and nephritis. The previous history suggested hypertension in her first pregnancy with abruptio placentae, accounting for the violent labor and death of the fetus. Such would be typical of preexistent nephritis exacerbated by pregnancy.<sup>3</sup> On the other hand, the situation was compatible with preeclampsia.

The Wassermann reaction was negative. Her arterial tension fell from 162/104 to 140/90 with the amyl nitrite test.<sup>15</sup> The blood had a hemoglobin content of 62 per cent (Newcomer), red blood cells 3,120,000; white blood cells, 7400. The renal function tests revealed:

1. Renal concentration test:

Maximum specific gravity = 1.017.

2. Urea clearance (maximum): 68 cc. blood cleared per minute.

3. Phenolsulphonphthalein excretion:

60 minims	45 per cent
120 minims	25 per cent
Total	70 per cent

4. Glomerular function (sodium ferrocyanide):

30 minims	8.4 per cent	Normal = 12 to 17 per cent
120 minims	6.1 per cent	8 to 12 per cent
Total	14.5 per cent	20 to 30 per cent

These studies demonstrate: (1) moderate arteriosclerosis; (2)

marked impairment of functional reserve in concentrating the urine; (3) impaired glomerular secretion; (4) normal urea clearance; (5) phenolsulphonphthalein excretion delayed; (6) severe secondary anemia. These facts are wholly compatible with a diagnosis of chronic nephritis and hypertension, exacerbated by pregnancy, but incompatible with preeclampsia. Although the renal function tests revealed no severe damage, the embarrassment was increased greatly by the added load placed upon the kidneys by pregnancy.

The patient was kept under observation in the hospital. Her blood pressure rose *gradually* to 185/120. Every effort was made to treat the anemia and her hemoglobin content rose to 79 per cent. Just before eight months, when the fetus was reasonably viable, she was delivered by cesarean section and sterilized. The placenta contained numerous small infarcts. Following delivery the arterial tension has remained high; now, six months postpartum, it is 150/96. The future course, typical of this type of nephritis in pregnancy, will be one of slow but persistent progression of the hypertensive disease and nephritis. The baby survived.

#### SUMMARY

Renal function tests are not only useful but necessary for proper study and evaluation in clinical situations involving the kidneys. They serve to measure the renal reserve capacity, to localize the site of greater injury and to reveal changes in the extent of renal damage.

The renal concentration test, which is the simplest to perform, is thus far the most sensitive indication of depletion in functional reserve. The urea clearance test is a more accurate guide to changes in function in advanced nephritis. Phenolsulphonphthalein excretion is grossly impaired only when damage is extensive. The glomerular function test with sodium ferrocyanide is still experimental; further study indicates that there is a real place for this procedure in our diagnostic armamentarium.

### DIAGNOSIS AND MANAGEMENT OF ANTEPARTUM FETAL DEATH

THE fetus like the fruit of a tree usually starts auspiciously, goes through a period of normal growth, and finally reaches maturity in a healthy normal condition; but like the fruit of a tree, it may encounter various pathological conditions which interfere with this normal development so that it may become deformed or die at any stage before reaching maturity. I shall consider only the recognition of the death of the fetus or embryo, and for various reasons which you will see, I shall divide these deaths into two groups: first, those occurring before quickening; and secondly, those occurring from quickening to term.

The diagnosis of life or death of an embryo or fetus is always of great importance. For the patient it may involve moral, physical, economic, and other problems but for the physician it becomes a problem of diagnosis to be approached with great caution, yet without fear. The subsequent conduct of the case naturally depends on the decisions reached by him.

**Before Quickening.**—A pregnant woman reporting shortly after conception shows practically no physical changes. We may have only the data that a menstrual period has been missed. In a woman of childbearing age, heretofore always regular, the significance of that statement is that she is pregnant. As the pregnancy develops, certain signs and symptoms with which you are all familiar become manifest, for example: nausea and vomiting, enlargement of the uterus, discoloration

of the vagina, breast changes, etc. All of these bear out that conclusion. Needless to say, the Aschheim-Zondek test is positive. Should death occur to the embryo in this early stage, one notes a change in these symptoms and signs. The breast symptoms disappear, nausea and vomiting cease, the uterus does not grow, in fact it may decrease in size, there may be brownish stains appearing on the clothing, vaginal coloring returns to normal, and the Aschheim-Zondek is negative. If this return to normal is noted by the physician who has seen the positive signs and symptoms of pregnancy in his patient, there should be little hesitation in arriving at the conclusion that the embryo is dead.

Death of the embryo usually has a salutary effect on the woman who suffers from excessive vomiting and this improvement alone is diagnostic. Should the patient report for the first time after the death of the embryo, when pregnancy signs and symptoms are negative, and the attendant has nothing for physical comparisons in the patient, the diagnosis still can be made by a careful history which shows that symptoms of pregnancy were recently present and have since changed. A uterus slightly larger than normal may or may not be significant. A negative Aschheim-Zondek under such conditions is of little value. Dr. Rezek of the Medical Department of the University of Illinois has recently shown that follicular changes in the ovaries of rabbits are characteristic when the urine of women with dead embryos or fetuses is injected as for the Aschheim-Zondek test.

Until now it would appear that I am referring only to pregnancy in the uterus. But the statements just made apply with equal value to pregnancies which have died in the tube. It applies also to pregnancies in the abdominal cavity which primarily started there and to pregnancies which began in the tube and later became tubal abortions, whose disrupted circulations resulted in death.

I have yet to find a train of symptoms which gives a clue to the diagnosis of embryonic death. Statements are made by DeLee and Litzman that they have noted a clinical syndrome

of malaise, anorexia, headache, loss of weight, chilliness, foul taste, bearing-down sensations, and increasing invalidism. This has not been my experience. These symptoms have not appeared characteristically in the hundreds of early intra-uterine and extra-uterine deaths investigated even when the dead products of conception were retained for many months. Authors have written up cases retained in the body for many years without mention of a single symptom in the above list. However, when infection complicates matters, such a picture, plus fluctuating febrile temperatures is the rule. All cases of extra-uterine deaths studied came to the operating table, some diagnosed as extra-uterine pregnancies and some not; the indication for the operation was the persistent symptom of pain.

Most intra-uterine early pregnancies are expelled spontaneously within a short time after death of the embryo and are treated as abortions, without diagnosis of life or death. Tubal abortions resulting in the death of embryo are numerous. It is wise, however, not to consider all of them dead. Evidence that they need not all be removed exists in the fact that many useful citizens are alive today although they were at one time in their lives nothing less than tubal abortions. They continued to thrive in their new surroundings among the intestines and developed to maturity. Laparotomy, of course, was necessary to deliver them.

Tubal abortions which die or those arriving at maturity and which die undelivered, frequently remain in the abdomen for many years without sufficient symptoms to require laparotomy. The Aschheim-Zondek in such cases should be a useful guide. In the absence of sufficient symptoms for operation, it indicates a *laissez-faire* policy, except when alive and approaching maturity. Radicals believe that such abnormal pregnancies are better removed immediately on diagnosis, regardless of the condition of the fetus, because of potential difficulties to be encountered later.

**From Quickening to Term.**—During this period there are present other elements in the fetus which have great value in determining its life or death. First in importance is per-

ceptible movements of the living fetus. A mother, who has once felt them during pregnancy, quickly misses them on their cessation. The history of such a change is significant but in itself not sufficient to establish the diagnosis of death. Very often I have been able to palpate fetal movements while the patient is on the table, and have the patient entirely unaware of their existence. However, such a finding is subject to error and requires corroboration by other methods.

The fetal heart tones are characteristic of life during this stage and are often heard distinctly as early as the beginning of the fifth month. Falls, with his intravaginal stethoscope, claims to hear them earlier than that. When once heard, the diagnosis of life of the fetus is assured; however, one of twins may die, its heart tones naturally disappearing, while the heart tones of the surviving fetus continues. The death of its twin remains unrecognized until delivered.

The disappearance of all heart tones, when they have once been heard by the physician in attendance, definitely points to the death of the fetus. Another important sign, even of greater value than the disappearance of fetal heart tones, is the indescribable silence over the abdomen, which one obtains when the fetus is dead. You have all probably encountered this stillness in the presence of fetal death. It is a silence which can literally be "heard," because of the way it stands out in auscultation of the abdomen.

A negative finding of considerable importance is the improvement in the patient's condition when there is associated toxemia. With the death of the fetus, hyperemesis improves and often disappears; edema is lessened and blood pressure drops. However, such findings cannot be considered 100 per cent positive. Corroborative evidence must be added.

In 1921, I brought out before the Chicago Gynecological Society, the fact that the x-ray can be used in determining this condition. World-wide corroboration of my findings and further experience with the x-ray, have convinced me that we have here means of obtaining conclusive evidence that fetal death really exists. As you have all noted in cases of stillbirth, the brain

is practically the first organ in the fetus to undergo degeneration. It follows then that the loose, enclosing skull covering the fetal brain collapses down on its shrinking contents, and when *x*-rayed, shows changes in contour characteristic of death. I have demonstrated this with a fetus externally on the first day following death, and intra-uterine as early as the third. Overriding of the skull bones with cephalic asymmetry are positive signs of intra-uterine fetal death and may be observed even before surface maceration.

There are those who require a longer time in order to be assured of such a diagnosis roentgenologically. They base their opinions on a comparison of the age of the fetus as shown by *x*-ray, and compare it with the age calculated from the date of the last menstruation. The difference in size indicates the duration of death. The chief objection to this method is that death must be present for a sufficient length of time to show this disparity in size and age. Elements of error based upon the fallacies of technic and calculation are always present.

Repeated *x*-rays at two-day intervals are found to be revealing not only in the changes which occur in the fetal skull, but the constant fixed posture maintained by the fetus throughout the period of observation. Such findings as angulation of the fetal spine and collapse of the thoracic cage are also considered of value but, I should say, only when there are associated skull changes. I believe these findings are present only in the utmost degrees of maceration and disintegration, and are secondary to those changes which occur in the fetal skull.

There are some investigators who claim that overriding of the fetal skull may appear in the living fetus before birth. I grant that, but only after the onset of labor pains or difficult lightening. Dr. Maurice Blatt shows the picture of a living microcephalic idiot, with overriding of the skull bones several years after birth. I mention this merely to point out that there are possibilities of error. Dependence on one sign alone is full of risk. A new life may be at stake as well as a reputation: therefore, I advise consultation for a division of responsibility.

All data must be assembled and studied before drawing conclusions and making the final diagnosis. The subsequent treatment may then be pursued without hesitation.

All too frequently we encounter patients in whom this unfortunate complication has occurred more than once. Habitual abortion or habitual fetal death then really becomes a serious problem. The patient with one accident usually becomes reconciled if her reproductive years lie ahead of her, but if no live birth results, she considers her losses more and more with the passing years and each loss more tragic than the one before. In such cases the internist also plays an important rôle in locating the etiologic factor.

The therapeutics of fetal death within the mother consists in removing the products of conception. In early uterine pregnancies before quickening the one- or two-stage abortion is indicated. Intra-abdominal pregnancies in this stage may remain quiescent and need not be hurriedly laparotomized; they may even be left alone. When necessary, those pregnancies beyond quickening should be removed by midline laparotomy just like ectopic pregnancies. The intra-uterine cases usually abort but if evacuation is desirable preliminary bags are employed (1 cm. for each month of pregnancy—five months, 5-cm. diameter; seven months, 7-cm. diameter, and so on). Following the expulsion of the bag, manual or instrumental removal can then be undertaken safely.

Hysterotomy, usually by the vaginal route, can be performed without great jeopardy to the mother, but such extensive surgery for this complication is rarely undertaken. The abdominal hysterotomy is too formidable a risk as the dead fetus and secundines are undergoing degeneration in the uterus and are a potential source of infection.

An intra-abdominal pregnancy which dies from quickening to maturity, as a rule, is sterile and may be considered a foreign body. Its hasty removal may lead to serious complication—especially if the placenta is attached to vascular structure—which themselves cannot be removed. If operation is performed the placenta should not be removed if it is attached

to intestines or other important structures. Ligation of the cord with catgut or silk close to the placenta with usual closure of the abdomen is sufficient.

One case with which I am familiar went to term with a normal-sized infant. Attempts to induce labor by bags were attempted on several occasions and given up because of technical difficulties. The pregnancy turned out to be intra-abdominal. The attending physician became ill and nothing was done for the patient for several years. Laparotomy was ultimately performed with removal of a cystic mass which contained all the bones of a normal-sized term fetus. The whole mass was then no larger than a grapefruit, pedunculated and readily removed. The site of the placenta could not be found as the rest of the abdomen was normal. The placenta was completely absorbed. A formidable operation became an easy one.

I mention this case only to show the harmlessness of allowing a dead fetus to remain unremoved. Each case, however, must be given individual consideration and in the absence of special indication should be treated with slow and deliberate methods.

For habitual death of the fetus at term, we have only the premature induction of labor. Associated diseases as syphilis or nephritis, of course, must receive appropriate treatment. When the cause is unknown, the handicap becomes greater. The high mortality rate of infants delivered by induction of premature labor makes one wonder if this operation should not give way to that of premature abdominal cesarean section.

## CLINIC OF DR. EDWARD A. ALLEN

### PRESBYTERIAN HOSPITAL

---

#### DIAGNOSIS AND TREATMENT OF PERSISTENT VAGINAL DISCHARGE

THE diagnosis and treatment of vaginal discharges is still frequently based on inadequate examinations and failure to establish definitely the etiological factor. I should like this morning to present several patients whose histories reveal the more common diagnostic errors and discuss with you how we may avoid them.

This little girl of eleven years illustrates very well the importance of an accurate history of the complaint, evaluation of the sequence of events and the gratifying results obtainable with simple procedures. Four years ago the mother of this youngster noticed more than the normal amount of discharge on the child's underclothing. The vulva was irritated and when the mother questioned her the little girl admitted that there was some discomfort during urination. Immediately the mother's suspicions were aroused and when further questioning elicited the information that her daughter had been playing during school recesses in an abandoned building near the school her fears were increased. When she learned further that several older boys also frequented the playhouse, suspicions turned into certainty that the discharge must be venereal in origin. Prompt medical advice verified this diagnosis and then began the long period of treatment for gonorrheal vaginitis. Four years of psychic trauma both to this child and her mother have followed. Due to the father's occupation, several changes in residence have been made during this time. In each new home the original diagnosis has been taken for granted and the treat-

ment continued. Four weeks ago the discharge began to change color and became brown. When we saw her first, two weeks ago, the discharge was profuse and contained gross blood. It was at once evident that we were not dealing with a gonorrheal vaginitis unless constant reinfection had occurred, because gonorrhea is not a chronic disease. This condition, as in the adult, runs its course and disappears even in the absence of treatment.

Finding the gonococcus in the vaginal secretion over long periods of time has, in our experience, always gone hand in hand with a definite history of reinfection. Methylene blue and Gram stains of this secretion failed to reveal the presence of the gonococcus. The complement fixation test was negative. On rectal examination an indurated area could be felt in the vagina, especially on the right side. This induration extended from the vaginal vault to the hymenal ring. With the patient in the knee-chest position, air was allowed to distend the vaginal canal. By carefully inserting this small Kelly cystoscope containing the proper illumination, a thorough inspection of the vaginal walls could be carried out without anesthesia. This large hairpin which I have was found with one leg of it almost covered with granulation tissue and grown into the right vaginal wall. Five minutes of ethylene anesthesia was sufficient for the removal of the foreign body. The mother says today that the discharge has entirely stopped. The patient either does not remember when or by whom this foreign body was inserted or still wilfully denies any knowledge of its presence.

Only about one half of the vulvovaginitis in children is caused by the gonococcus. The remainder are of nonspecific origin and in about 10 per cent of instances are caused by foreign bodies. In our clinic here in Rush Medical College devoted to vulvovaginitis, we have found other hairpins, safety-pins, shoe buttons, balls of cotton, beans, and a buffalo nickel. Small articles of almost every description have been reported in the literature as a cause of vulvovaginitis. If the gonococcus is not clearly demonstrable in the smear, or if

excessive secretion continues for long periods of time, rectal examination may at once reveal the diagnosis. Inspection through a vaginoscope with the patient in the knee-chest position can be carried out usually without anesthesia even in babies, if proper care is exercised in insertion of the instrument. This procedure should never be omitted in the diagnosis of nonspecific vulvovaginitis.

This patient illustrates very well a type of vaginal discharge that has become increasingly frequent in the last few years. The history of her complaint is quite characteristic. Three years ago the patient consulted her physician concerning a moderate leukorrhea. At that time an erosion of the cervix was found and an extensive radial cauterization of the cervix was done. For about eight months following this treatment the patient was free from discharge. The return of the discharge was abrupt and has recurred intermittently during the past two years. The discharge now present has contained small amounts of blood during the last three weeks. The patient complains of considerable burning in the vagina and smarting about the introitus.

Pelvic examination reveals normal pelvic findings except that the cervix seems to be slightly enlarged and succulent. As we view the cervix through this bivalve speculum, you will notice the distortion of the external os and here on the right side its lips are glued together by thin adhesions. The further distortion of the cervical canal can be determined with this soft probe which we will introduce gently as far as the internal os. You will notice, when the probe is withdrawn, a rather large amount of thick leukorrheal discharge tinged with blood escapes. This fluid has been pent up behind the partial or at times probably complete stenosis of the cervix. Increased tension has at times become sufficient to overcome the obstruction and this explains the intermittent character of the discharge. The damming back of secretion, of course, predisposes to infection, maceration of the endocervix and as a result increased secretion which now has become streaked with blood. We shall gently dilate this cervix with smooth graduated

dilators to overcome the obstruction and prevent as nearly as we can further trauma to this already damaged cervix. Subsequent contraction of this scar tissue, however, is the general rule and repeated dilatations are usually necessary until the canal of the cervix is completely healed but still patent enough to permit free drainage. We do not favor extensive cauterizations of the cervix and especially those which involve the cervical canal. Clinical cure can usually be obtained by wiping off the external erosions of the cervix with the nasal snare cautery point without invasion of the cervical canal.

I should like at this time to present to you 3 additional patients whose clinical histories of vaginal discharge are almost identical. The etiological factors, however, are different in each individual. These patients represent that large group of individuals having nonspecific vaginitis which all of us encounter in our daily practice. They are very important not only as gynecological diseases but, since they may involve the urinary tract, gastro-intestinal tract, perianal region and, in the male, the prostate, they become of general interest.

These 3 patients all relate this similar history: following the last menstrual period a profuse vaginal discharge began. This was accompanied by pronounced burning and itching in the vagina and about the external genitalia; lumbosacral backache and a bearing-down sensation in the pelvis have become more severe daily. Frequency of urination has been increased, and in this first patient whom we shall now examine nocturia has become a very distressing symptom.

You will notice here as we inspect the vulva and perianal region that the skin is reddened and excoriated. The superficial layers are slightly macerated due to the constant irritating discharge that is present. This discharge is watery and the small bubbles contained in it at once give us the clue to its origin. Therefore, before bimanual examination is undertaken, specimens of this discharge will be obtained by collecting it in the posterior blade of the speculum. Contamination of this secretion with examining jelly, and especially glycerin, would vitiate our results. In like manner, recent vaginal medication

or even a plain water douche may render immotile the flagellates which we confidently expect to find here. It can readily be seen that this discharge does not resemble the yellowish puslike discharge caused by the gonococcus. It has a greenish tinge and is more watery and bubbly in consistency. However, we will make the usual smears for subsequent staining as occasionally gonorrhea and *Trichomonas vaginitis* occur together. If we place a small drop of this secretion on the slide and cover it with a coverslip, a thin layer of material results.

Fig. 19 - *Trichomonas vaginalis* as seen in the unstained secretion. The flagella are usually bipolar in arrangement.

If this layer remains too thick for satisfactory microscopic examination, slight pressure on the coverslip or the addition of a drop of normal saline will suffice to thin it. Now under high dry magnification and reduced illumination a careful search will be made for motile organisms. This motion, as you see, is of a whipping, lashing character which violently agitates the cellular debris and clumps of coccoid organisms which are present in large numbers. These motile organisms are flagellates called *Trichomonas vaginalis* (Fig. 19). They are found

in patients presenting symptoms of vaginitis many times more frequently than is the gonococcus. They cannot be identified in the usual stained preparation but should be recognized by their motility and identification of the flagellates while in motion. Special stains have been advised by several investigators

Fig. 20.—The marked bilateral dilatation of the ureters in this patient was apparently the result of the trigonitis. The typical edema about the ureteral orifices was very marked.

but, at least in our experience, the fresh secretion remains the best means for identifying these organisms. You will notice that this secretion bathes the external genitals. If we depress the posterior wall of the vagina the external urethral orifice gapes and the secretion actually seems to be aspirated into it. This may well account for the typical urethritis found so fre-

quently associated with this infection. Extension upward into the bladder seems to be almost a foregone conclusion. We must, however, bear in mind the possibilities of a direct extension from the adjacent anterior fornix of the vagina. About one half of these patients present a typical trigonitis. When viewed through the cystoscope these areas are usually confined to the urethra and trigone and not infrequently involve the ureteral orifices. In this x-ray film (Fig. 20) you will see a bilateral hydronephrosis for which we could find no other cause than the marked edema about the ureteral orifices. This patient was relieved of all of her symptoms following treatment of the *Trichomonas* in the vagina and refused to allow even a follow-up intravenous pyelogram. This edematous area in the bladder mucous membrane is fluffy, pale, and in some areas resembles a leukoplakia. Scattered over the surface of the lesion but more pronounced around its periphery are many small petechial hemorrhagic spots. These spots suggest the presence of the streptococcus. We have isolated from the catheterized urine of these patients and also from tissue removed with the suction curet large numbers of hemolytic streptococci. Histological examination of these bits of bladder mucosa reveal a thickening and vacuolization of the squamous cell layer.

When the excess secretion is wiped from the vaginal walls the mucous membrane is red and edematous. Scattered everywhere, but particularly in the anterior fornix, are many petechia-like spots similar to those we have just described in the bladder mucosa. The descriptive term of "strawberry vagina" has aptly been applied to this condition. Biopsy specimens removed from these hemorrhagic areas reveal a subepithelial infiltration with leukocytes and coccoid organisms. Invasion of adjacent tissues, such as the bladder and parametrium by means of the lymph or blood vessels, may offer a logical explanation of the spread of the infection. That the infection does spread we are quite certain. We have observed definite clinical and palpatory evidence of invasion developing in many of these patients for which no other explanation than the vaginitis could be found. Numerous patients have begun to bleed

profusely or intermittently soon after the onset of the vaginitis. The increased blood loss has been controlled as soon as the vaginitis has been adequately treated. During the course of the disease several women have developed severe pain and rigidity in the lower quadrants accompanied by elevations in temperature and the leukocyte count. Pelvic examinations at this time revealed tender swellings in the region of the adnexa which had previously been normal to palpation. We have isolated the typical streptococcus, which is regularly associated with *Trichomonas vaginitis*, from the acute swellings of the Bartholin gland found in several of these patients. Erosions of the cervix which are frequently found in conjunction with *Trichomonas vaginitis* may heal completely when the vaginitis has been cured. However, it may be necessary in the later stages of the treatment to lightly cauterize these lesions for the complete eradication of the vaginal infection. Cauterization should not be done in the acute stages as acute pelvic cellulitis may be the result.

The treatment of *Trichomonas vaginitis* is still empirical. Good results can be obtained in from 50 to 80 per cent of the patients with any one of several procedures. The remaining 20 to 50 per cent recur at intervals, often for many years. Until further investigation clears up the primary mode of infection and probable methods of reinfection, better results in treatment will likely not be obtained. The fundamental rules governing almost all of the generally accepted plans of treatment are the same. The vaginal walls and introitus should be scrubbed free from secretion either with green soap or a gauze sponge. These surfaces should then be sprayed or painted with medicinal substances which are not too irritating to the vaginal mucous membrane. These medicaments may be in solution, powders, pastes or in the form of vaginal suppositories. The substances most commonly advised are the dyes, as methylene blue either in aqueous solution or mixed with glycerin. picric acid  $\frac{1}{2}$  per cent in solution or contained in suppository form, drying powders such as kaolin or fuller's earth alone or in combination with alkalis such as sodium bicarbonate. Lac-

tose and citric acid are more recent additions to the list. Many of these powders contain one of the arsenicals such as stovarsol or carbarsone in proportions of 2 parts to 7 parts of the powder. Lactic acid forms the basis of several of the jellies or pastes in common use but has a probably wider use in the vaginal douche and can be used by the patient daily. The powders must be applied or insufflated by the physician, although recent tablet forms are receiving wider attention.

This patient will be placed on the following treatment: the vagina and external genitals will be cleansed with tincture of green soap and then thoroughly dried with gauze sponges. Through the speculum we can then spray the walls with this powder composed of 2 parts of stovarsol to 7 portions each of sodium bicarbonate and kaolin. The distribution of the powder should also include the introitus. We have found this little spray can, which is ordinarily used for insect powders and obtainable at any drug store for 10 cents, very satisfactory. The patient should be instructed to protect herself with a pad as the powder liquefies and produces a profuse discharge. Tomorrow morning and each morning thereafter the patient should take a 2-quart warm water douche to which has been added 1 drachm of lactic acid. These treatments should be continued daily for at least one week. At the end of that time the patient may carry on her treatment at home by inserting into the vagina upon retiring a vaginal suppository containing 1 per cent picric acid. The excess material from the suppository should be removed the following morning with the lactic acid douche. Following the next menstrual period the powder insufflations should be carried out again for a few days because at this time recurrences seem most likely to occur. This general scheme should be followed for at least three months, gradually decreasing the frequency of medication. The douche should be sterilized from time to time as we have encountered several recurrences which have unquestionably been on this basis. Continued effort to increase the general resistance by rest, high caloric and vitamin diets will be advised. The husband will, if possible, be examined by two tests, one for the presence of *Trichomonas* or a nonspecific organism.

The second patient of this series you will notice presents the same clinical symptoms with the exception of urinary distress. Careful inspection of the external genitals, however, reveals an entirely different picture. The introitus is reddened and edematous with tiny areas here and there where the superficial layers of the skin have been removed by scratching. The amount of external discharge is entirely within normal limits. If we, however, inspect the vaginal walls we see that they are

Fig. 21.—The typical branched, segmented mycelia of yeast stand out clearly in this specimen stained with the Gram stain. The bud forms are characteristic enough to warrant identification even in the absence of the mycelia.

covered everywhere with a thick, cheesy, almost membrane-like material occurring in plaques. When these plaques are wiped away, a raw surface is found beneath them and occasionally minute bleeding points appear. The appearance of these vaginal walls is very similar to the condition found in the mouths of babies with thrush. We might well speak of this condition as vaginal thrush, because the infecting organism is one of the varieties of yeast. You will notice here in the unstained secretion the long mycelia with their rounded ends and

branching filaments with many new buds in the process of growth (Fig. 21). Methylene blue or Gram stain will more clearly demonstrate the organism if doubt exists as to their presence. At the same time it will give us material for examination for the gonococcus.

The treatment of vaginitis caused by the yeasts is more simple than that of *Trichomonas* vaginitis. The aniline dyes, such as gentian violet, seem to be almost specific. A few applications of a 1 per cent aqueous solution of gentian violet

FIG. 22.—With dark-field illumination the spirochetes in this vaginal secretion could be seen in large numbers. They are probably of the type *Treponema calligyrum*.

applied to the vaginal walls and introitus is usually sufficient. However, the urine should always be examined for sugar when this infection is present. It is a very common affliction in renal and true diabetes. Cure of the vaginitis is difficult or impossible until the quantity of sugar in the urine is reduced. Daily douches containing  $\frac{1}{2}$  drachm tincture of iodine should be continued until after the next menstrual period.

This last patient, although she complains of almost identical symptoms as the other two, is afflicted with a very unusual and

interesting type of vaginitis. You will notice that the discharge is very profuse. The discharge is of the same general character as that caused by *Trichomonas* except that there are no bubbles present in it. The intense irritation about the vulva has made it difficult for the patient to walk or remain seated. Intercourse, even if attempted, has been so painful that the dyspareunia has become a major problem. In fact, dyspareunia is often the most important complaint of patients afflicted with any type of vaginitis. Any patient who complains of dyspareunia should be carefully examined for the presence of vaginal infection. The far-reaching consequences of this disability require its immediate cure. Careful examination of this secretion has failed to reveal any *Trichomonas* or yeast organisms. The stained preparations are negative for the gonococcus. Under dark-field illumination we see that it is swarming with spirochetes, probably of the strain *Treponema calligyrum* (Fig. 22). Slides prepared from this secretion and stained with Gram stain reveal the organisms in great abundance. Several strains of spirochetes besides that causing syphilis are occasionally found in the vagina. This patient's blood Wassermann and Kahn test were negative. Her symptoms will promptly disappear following a short series of vaginal insufflations with the powder that we have just described for *Trichomonas vaginalis*.

## CLINIC OF DR. NORRIS J. HECKEL

### PRESBYTERIAN HOSPITAL

---

#### TRICHOMONIASIS OF THE GENITO-URINARY SYSTEM

*TRICHOMONAS vaginalis* infestation of the male genital tract is now being recognized with greater frequency, and we observe that *Trichomonas prostatitis* is no more such a rare condition. Recently, it has also been observed that *Trichomonas vaginitis* in the female may cause associated pathologic changes in the bladder and urethra.

To illustrate some of the more important findings in my studies on *Trichomonas vaginalis*, as found in the genito-urinary system, I am presenting these patients.

**Case I. *Trichomonas Prostatitis*.**—Mr. B., age fifty-one and married, is referred to me in order to determine if the prostate gland may not be the cause of recurrent attacks of *Trichomonas vaginitis* in his wife.

Except for a slight urethral discharge and occasional nocturia, this patient has no other urinary complaints.

The examination of the external genitalia reveals a very small external meatus from which a white mucoid discharge is obtained. The rectal examination shows the prostate to be slightly enlarged, especially in the left lobe with evidence of periprostatis; the right lobe is normal. The microscopic examination of the urethral smear reveals no *Trichomonas*, however, in the prostatic fluid *Trichomonas* and 2+ pus are found. The urine is normal with the exception of a few pus cells, no *Trichomonas* are present. Stained smears from the urethra and prostatic fluid reveal no intracellular nor extracellular diplococci. On exploring the urethra with diagnostic

sounds, extensive multiple strictures are found. Therefore, we can definitely say that this patient has *Trichomonas prostatitis* and strictures of the urethra.

Our technic in searching for *Trichomonas* is very simple. The prostatic fluid or urethral discharge is collected directly on a glass slide and spread not too thick. An ordinary cover slip is placed over the material and an oil immersion lens is used for observation. For office routine this procedure takes little time and, in our opinion, has been just as accurate as the hanging drop, or other more elaborate methods. One examination is not sufficient to rule out the possibility of *Trichomonas*. Searches on several different occasions should be made before a negative diagnosis is given.

In the treatment of this patient a meatotomy is first done. Then he is given prostatic massages and urethral sounds twice a week, and heat, either in the form of diathermy or an electrical heater, applied to the prostate. Urethral instillations of 20 per cent neosilvol, or irrigations of potassium permanganate, 1:3000, are used. This procedure is carried out until the prostatic fluid is free of *Trichomonas* and pus cells. In the prostate and urethra the *Trichomonas* usually disappear early, that is one or two weeks after the treatment has begun. However, the pus cells and other bacteria, usually streptococci, may be present for as long as three or four months, and it is important to continue treatment regularly until the prostate is entirely normal.

In a problem such as this, an attempt should be made to establish the primary source of the infestation if possible and thereby recognize the factors which may predispose to recurrences. In this particular patient, it is apparent since he and his wife are both infested that one may be reinfesting the other. Unquestionably, in such cases, the reinfestation is by sexual intercourse, and if either the male or female is cured, and no attempt made to search for the possibility of infestation in the other, then recurrent attacks can and do occur. Therefore, in this instance, we will advise against sexual intercourse during such time as the vaginitis, urethritis, or prostatitis is active.

In my second case, the opposite picture is present—the wife is not infested with *Trichomonas*.

**Case II. *Trichomonas* Urethritis and Prostatitis.**—This patient is forty-nine years old, married, and presents himself complaining of urethral discharge and burning of five days' duration. He fears the return of an old gonorrheal urethritis. Extramarital exposure is denied.

FIG. 23.—Prostatic fluid showing pus cells and *Trichomonas*.

The examination, as you see, reveals a copious amount of frothy, milky urethral discharge. The meatus is red. A small amount of the discharge is placed on a slide and examined—it is filled with *Trichomonas*. The rectal examination shows the prostate to be normal; however, the prostatic fluid contains many *Trichomonas* and pus cells (Fig. 23). Therefore, the diagnosis is an acute *Trichomonas* urethritis and prostatitis.

The treatment of this patient will be very similar to the procedure followed for the first patient, except that during

the hyperacute stage, which is usually three to six days, he will be given only sitz baths and alkalis such as bicarbonate of soda, or potassium citrate. When the acuteness of the attack subsides, then urethral instillations and prostatic massages will be carried out.

Many times it is difficult to evaluate in what way the infection occurred. In an effort to determine the origin of the infestation, the patient's wife has been examined and repeatedly the smears show no evidence of *Trichomonas*.

During the last few years, I have seen 5 cases of *Trichomonas prostatitis*. I have also had the opportunity to examine many husbands whose wives are infested with *Trichomonas* and it is surprising to find that a large number, although no *Trichomonas* can be found, do have an infected prostate, and in the culture from the prostatic fluid streptococci are usually found. According to some authors, these findings would be explained by the fact that the *Trichomonas vaginalis* itself is not pathogenic but occurs only as a secondary invader or in symbiosis. Those who hold this belief are of the opinion that the streptococcus is the pathogenic organism.

The majority of these men presented no genito-urinary symptoms, and had not an examination been made, the infection would not have been recognized. Usually the symptoms of *Trichomonas prostatitis* are the same as those of a nonspecific prostatitis; that is, a persistent urethral discharge and morning drop, associated with other various genito-urinary complaints. The condition, however, may start as an acute urethritis in which the discharge has a frothy, bubbly appearance, burning and frequency of urination, and an itching or smarting of the urethra may be present. I have not as yet seen a patient with a *Trichomonas urethritis*, who did not also have an associated prostatitis. In the rectal examination, the prostate may be entirely normal in size, shape and consistency, or there may be areas of hardness and infiltration. It is never tender nor swollen as in acute gonorrheal prostatitis. In venereal infections those having nonspecific urethritis and prostatitis are not a small number, and if more careful bacterio-

logical examinations are made, I am sure that in a larger percentage of the cases *Trichomonas* infestation will be found.

My third case is that of a woman with recurrent *Trichomonas* vaginitis in whom the urinary symptoms are pronounced.

**Case III. Recurrent *Trichomonas* Vaginitis.**—Mrs. H., aged forty, has been treated elsewhere during the past six months for recurrent attacks of *Trichomonas* vaginitis. These attacks have been accompanied by aggravating urinary symptoms of frequency every two or three hours, nocturia four or five times, with burning and dysuria. Here I should like to stress the importance of obtaining a careful and accurate history. Because of the severe vaginal symptoms of leukorrhea, scalding, and dyspareunia which frequently occur in these patients, definite questions must be asked in order to elicit information concerning the urinary complaints.

This patient has had a complete and thorough examination of the gastro-intestinal tract, teeth, tonsils, Bartholin and Skene glands as a possible focus for the recurrent vaginitis attacks, and all are negative. In the bacteriological study of the cultures taken from the vagina and cervix, streptococci have been found. I might also add that the same strain of streptococci has been cultured from the prostatic fluid of her husband, who, although no *Trichomonas* have been found, does have an infected prostate.

Because of the patient's urinary symptoms a cysto-urethroscopic examination is done. The urine, as you see, is clear and sparkling and a specimen is collected for bacteriological study. Your attention is called to the normal capacity of the bladder. This is an important observation to be used in the differential diagnosis from elusive ulcer in which the bladder capacity is greatly diminished.

The pathologic changes are seen on the base of the bladder in the region of, and anterior to the trigone. In some cases these changes may extend beyond the trigone and involve both the ureteral orifices; in others may be limited to the internal urethral sphincter. Observe the raised, granular, fluffy and

crepelike appearance of the bladder mucosa. It is a dull, pearly gray, and resembles somewhat the appearance of leukoplakia. The borders of this area can be sharply outlined from the normal mucous membrane. Notice the small petechial hemorrhages around this region which appear very similar to the surface of a strawberry. These changes look similar to those found in the vaginal vault of many patients with *Trichomonas vaginitis*. As the cysto-urethroscope is withdrawn into the urethra, note the marked edema around the internal urethral orifice, and the pronounced changes similar to those in the bladder.

This cystoscopic picture is seen quite frequently in *Trichomonas vaginitis* and I feel that in patients who complain of lower urinary symptoms, if these findings are observed, a careful search of the vagina should be made for *Trichomonas*.

In summarizing the condition of this patient, we find two possibilities for the recurrent attacks of the vaginitis. First, although *Trichomonas* were not found in the prostatic fluid of the husband, he did have an infected prostate and the same strain of streptococci was isolated from the prostate as was found in the vagina and cervix of the wife. He, therefore, may be the cause of his wife's recurrent attacks. Second, the cause may be found in the pathology of the urethra and the bladder. I have seen patients in whom, after the associated pathology in the urethra and bladder was cleared up, there have been no more recurrent attacks.

In the treatment of this patient until the acute condition subsides, we will follow this procedure: she will be given sitz baths, 2 or 3 daily, and internal medication of oil of sandalwood 5 minims, t.i.d., and alkalis such as sodium acetate 20 grains, or bicarbonate of soda, four times daily. Then the bladder is irrigated with an oxidizing agent such as 1:3000 solution of potassium permanganate followed by instillation of 2 to 3 ounces of 15 per cent neosilvol, or 20 per cent argyrol, twice a week. At the same time, topical applications to the urethra of 2 per cent silver nitrate solution, or  $\frac{1}{2}$  of 1 per cent zinc sulphate are used. If urethral pockets or other per-

sistent ducts in and about the urethra are present, it may be necessary to fulgurate them. The second part of the treatment will be directed to the husband and the prostatitis treated as previously outlined.

#### CONCLUSIONS

1. Each of the three patients presented to you illustrates an interesting phase of the *Trichomonas vaginalis* infestation.

2. The first is an example of the infestation probably through sexual intercourse, since both the husband and wife are infested.

3. The second patient illustrates an infested prostate and urethra, but no infestation in the wife. Furthermore, the history and examination of husband and wife in this instance give no solution as to the source of the infestation.

4. In the third case, which is that of recurrent vaginitis with urinary symptoms, we find first that while *Trichomonas* were not found in the prostate gland of the husband, a prostatitis was present, offering a possibility for the cause of the recurrent attacks of vaginitis. Second, the associated changes in the urethra and bladder indicate that the recurrences may be caused by these findings.

5. It cannot be too strongly emphasized that repeated examinations of the urethral discharge or the prostatic fluid must be made in many instances in order to find the *Trichomonas*.

6. In patients with so-called "nonspecific" urethritis and prostatitis a more careful examination will reveal a higher percentage of *Trichomonas* infestations.

HOSPITAL

---

### PERNICIOUS ANEMIA

#### DIAGNOSIS

In October, 1931, Mr. J. D., a sixty-four-year-old electric car motorman, walked into the out-patient department for an examination. No, he had no complaints; he had noticed only slight shortness of breath while walking to work, but the boys at the shop had told him that he was losing his usual ruddy complexion. Except for a slight pallor, physical examination failed to reveal any important indication of the presence of an illness. His color was fair, but in a good light the sclerae appeared to be slightly icteric. The examining physician, however, was not satisfied to do the customary routine examination of the urine and dismiss his patient with a tonic, a word of encouragement and a diagnosis of psychasthenia. He requested a blood count. This revealed a red blood cell level of 1,000,000 cells per cubic millimeter! Furthermore an examination of the stained blood film revealed a preponderance of large cells with many very large and oval-shaped forms and a fair number of pear-shaped and tailed forms.

Here then, reasoned the careful examining physician, is a man who walked into the hospital after his customary early morning run on his car with a red blood cell count of one million—certainly not a hypochromic type of anemia—for no one with this type of anemia and such a blood count would be out of bed. Then, too, there was evidence of a macrocytic anemia with pear-shaped cells and evident icterus of the sclerae. Even in the absence of a history of sore tongue or glossitis and disturbances which result from neural damage, the examiner felt justified in making a diagnosis of pernicious anemia and convinced the patient that his condition warranted hospitalization for treatment.

In the hospital the examiner's diagnosis was further con-

firmed by means of a fractional gastric analysis which failed to show free hydrochloric acid in any specimen even after the injection of histamine and also by the observation of the prompt and striking increase and decrease of the reticulocytes of the blood during a period of ten days following the intramuscular injection of a highly potent solution of liver extract. This patient with continued intramuscular therapy has been maintained in a normal state of health with a normal red blood cell level (5,000,000 or more cells) and has been able for more than five years to continue at work.

Therefore, because the examining physician was aware of the importance of an examination of the blood as well as the urine, a puzzling problem was solved and the development of complications which might have occurred through delay in treatment was avoided.

With the appearance in a patient of the characteristic clinical signs and symptoms a diagnosis of pernicious anemia may be made readily and with confidence. Laboratory studies of the blood may then be utilized merely to confirm the diagnosis and to indicate the severity of the anemia or to demonstrate the course of improvement of the blood following treatment. Unfortunately, however, cases presenting a typical picture of this disease represent only a portion of those who will present themselves for diagnosis. If one is to avoid overlooking those cases which do not present the characteristic clinical picture of pernicious anemia, it is important to study the blood routinely. The average physician equips his office so that routine examinations of specimens of urine may be made; but how many are equipped to make even the simplest blood examination by an accurate method?

The importance of a satisfactory examination of the blood is illustrated by the case of one of my patients, Miss R. O., a high school teacher in one of our large cities, who had consulted 5 physicians because of poor health. She was advised by the last one consulted to obtain a year's leave of absence and to travel for a much-needed rest. Her difficulties steadily increased during the trip until finally she collapsed in a small

town in India where the only physician for miles around made a diagnosis of pernicious anemia and started liver therapy. None of the first 5 physicians consulted had made any sort of examination of her blood.

Information sufficient to establish the presence of anemia will be obtained by a determination of the hemoglobin level. This may be done with reasonable accuracy by the use of a standardized Sahli apparatus which is inexpensive and also simple to use. Further indication of anemia may be obtained by even a brief study of a stained film of the blood. In order then to determine the cause for, or type of, anemia present, careful questioning as to loss of blood from hemorrhoids or, in the case of female patients, from the genital tract is essential and the necessity for a guaiac test of the feces to detect hemorrhage from the gastro-intestinal tract cannot be over-emphasized.

On the other hand, demonstrable anemia may not be present as the earliest evidence of pernicious anemia. Consequently it is important to bear in mind constantly that a rather persistent sore tongue or mouth occurring in a patient with no obvious roughening or abnormality of the teeth to account for the irritation, which has not been controlled by the customary local applications, may be the first evidence of this disease.

The typical tongue of this disease, rarely simulated by that occurring in any other anemic state, with the possible exception of sprue, either tropical or nontropical, is clean and almost never coated. Rarely are there localized ulcerations as in canker, but to the contrary the sides or even portions of, or the entire, surface may appear inflamed, with a beefy-red color and may often be distinctly glossy. The pale, smooth tongue may at times be present but is more likely to be observed in hypochromic anemia. The glossy, inflamed areas, wherever present, are highly susceptible to irritation. Hot or "sharp-tasting" foods, salt and the like may produce such irritation that the food intake becomes limited. Patients using dentures find difficulty in wearing them, consequently the

food intake is decreased. The sufferer tries one set of dentures after another hoping each time to discover some fault in the previous ones which would cause the irritation of the mouth. These changes in the mucous membranes may precede by months, or even a year or two, severe anemia or other evidences of the disease, and may persist constantly or intermittently for weeks, months or years, failing to respond considerably or permanently to any treatment other than that specific for pernicious anemia.

Although the sore mouth or glossitis is perhaps most frequently observed as the forerunner of the disease, disturbances resulting from neural damage are not infrequently present as the primary evidence of trouble and may occur, though rarely, in the absence of obvious blood changes. Because of the variations in neural disturbances and the bizarre or even "atypical" picture occasionally encountered, one must constantly be on the alert to recognize them as they may be symptomatic of pernicious anemia. Let us realize in the first place that their permanency rather than their extent is important. In pernicious anemia transient disturbances rarely, if ever, occur. Although numbness or tingling or both may involve only a hand or even two fingers of one or both hands, these will be persistently noted throughout the day and the waking hours of the night, whereas transient disturbances of a similar sort may be observed by the patient with hypochromic anemia or without anemia.

Numbness, tingling or a combination of the two are perhaps the most commonly described neural symptoms, and as suggested above, they may be limited in distribution or may involve both hands, both feet, and even extend well up onto the abdomen and back. As this condition becomes more marked, the sense of touch may be impaired. Not infrequently the patient complains of an inability to feel the floor with the feet while standing, or there may be a sensation as of walking on a thick carpet, or, if paresthesias are present, of walking on eggs or pointed stones. In one patient, a carpenter, the numbness of the hands became so intense that he was unable

to feel the handle of a hammer in his hand. As he glanced at the head of the nail to strike it, his grip on the hammer would be lost, and he would find it on the floor.

Paresthesia of the hands may become so severe that it is practically impossible to use the fingers unless protected. For this reason one patient constantly wore gloves. A housewife became practically an invalid owing to the excruciating pain induced even by touching her knife and fork at meal time.

Other common complaints are those of tightness and coldness of the extremities. Patients often describe these sensations by saying that they feel as though there were tight bandages wrapped about the legs. One patient said he felt as though he were standing in a cold stream in hip boots; another said that her hands felt as though they were in cold water with tight rubber gloves on.

The locomotor difficulties are more readily understood by the examining physician than are the neural disturbances which produce only subjective complaints. Locomotion may be altered at times because of the weakness resulting from severe anemia or because of the severe numbness previously described. With involvement of the lateral columns of the spinal cord, however, a more severe locomotor difficulty will be present. Either a spastic or flaccid paralysis may occur. Spastic difficulties are most common and occasionally are of such a nature that the knees may be permanently flexed, or the thighs may be tightly drawn together, or crossed. The reflexes are typically altered depending upon the type of involvement, but alterations in skin, tactile, pain and temperature sense rarely occur. In the presence of marked locomotor disturbance the ability to recognize tuning fork vibration over the tibiae is almost always lacking.

Jaundice is rarely present early in the course of the disease but may be observed in untreated patients with red blood cell levels of about 2,000,000 or less. The presence of jaundice produces the rather typical lemon or grapefruit colored pallor with the yellow sclerae which should at least suggest a diagnosis of pernicious anemia. At one time this jaundice was

thought to have been caused by unusual hemolysis of the red blood cells, but in view of our present knowledge of the disease it seems more logical to relate this, at least in part, to decreased utilization of the bile pigments.

### FAMILIAL INCIDENCE

The occurrence of pernicious anemia in two or more members of the same family group has often been noted, and such a tendency has been notable in my own series of patients. I wish to present briefly a few interesting examples of this.

Miss D. R., a school teacher, had developed the disease at the age of forty and was started on parenteral liver treatment, which has been continued faithfully for nearly five years with complete control of all symptoms. Several years after the onset of her illness she brought in her mother, then seventy-five years of age, for examination because of the occurrence of symptoms similar to those which had originally led her to seek medical advice. A diagnosis of pernicious anemia was obvious also in the case of the mother and now both receive treatment.

Miss N. S., a fifty-nine-year-old seamstress, who had been treated in the blood clinic for several years, brought in her fifty-six-year-old sister for examination because of symptoms similar to her own original ones, and again a diagnosis of pernicious anemia was readily made. Both these sisters have now continued parenteral treatment in the clinic for five years with satisfactory control of those disturbances primarily related to the anemic state. It is interesting to note, however, that both these sisters also have hypertension of moderate degree.

A third case of rather noteworthy interest is that of Mrs. F S, who is able to trace the occurrence of pernicious anemia through five generations. A cousin (the daughter of the patient's mother's sister) is known to have had pernicious anemia, and this disease also exists in a distant relative who is descended from a common ancestor eight generations back in the relative's family and nine generations from Mrs. S.

One point of particular interest in the case of Mrs F S is the certainty of diagnosis through so many generations. This is because of the fact that the same symptoms, soreness of tongue and mouth, and extreme hyperesthesia of the fingers and hands, had been recorded during the course of a fatal (in all except the last case) illness, associated with anemia, in each patient. Mrs F S, now seventy years of age, is one of five children, three of whom have had pernicious anemia. She has three adult children, none of whom has shown signs of this disease. Two sons although married for several years have no children; the wife of one had a child by a former marriage. The daughter, the patient's third child, had one child after being married for nine years.

There has been a steady trend toward fewer and fewer children with each generation so that the family is steadily decreasing in number. Each of the victims of the disease, except those in this generation who have had the advantage of liver therapy, has died before the age of fifty.

### TREATMENT

The next case which I wish to present is that of Miss B. S., a fifty-two-year-old cook, who first came to the blood clinic in April of 1936, with a normal red blood cell level (5,000,000 cells per cubic millimeter) and apparently in splendid health except for evidence of moderate locomotor difficulty and a complaint of persistent numbness of the hands, feet and legs up as far as the knees. Approximately eight months previously a diagnosis of pernicious anemia had been made while she was in another hospital. The chief complaint at that time, other than some degree of anemia, the severity of which she does not know, was extreme locomotor difficulty so that she could neither stand nor walk without aid.

While in the hospital treatment by means of intramuscular injections of liver extract was started. This consisted of injections of 5 cc. of a solution of liver extract of low concentration twice a day for about two months, after which time she received a similar injection once a day until she entered our blood clinic eight months later. During this time the injections were given by a district nurse whose daily charge was fifty cents.

This case illustrated two important points. In the first place we must all agree that an adequate amount of liver substance was administered to produce and maintain a normal red blood cell level (5,000,000 or more red blood cells per cubic millimeter). In the second place as was to be expected from the use of a sufficient supply of liver substance to maintain the blood at that level regardless of the method of administration, an improvement in locomotor and other disturbances caused by neural damage occurred, and we find the patient returned to a rather satisfactory state of health.

But what has it cost this patient, dependent upon her own earnings for a livelihood, to obtain this amount of improvement? The daily cost of liver extract (on the basis of 1 injection daily of 5 cc.) was 62½ cents. In addition to this she paid 50 cents for each injection. Thus her actual expense for three hundred and sixty-five days would be \$410.63! This amount does not take into consideration the original cost of hospitalization, physician's fees, nor her loss of earning power

during this time, as it was practically impossible for her to work and receive the daily injections.

What a contrast to her experience is that of the patient in our blood clinic who finally convinced her of the needlessness of such treatment and persuaded her to arrange for subsequent treatment in the clinic. His case is as follows:

Mr. W. P., a war veteran, forty-six years of age, who had essentially comparable neural disturbance, except that locomotion was less strikingly affected, has been under treatment for four years,, receiving injections of 3 cc. of a concentrated solution of liver extract at intervals of slightly more than four weeks. In order to maintain his blood at a level constantly above 5,000,000 cells per cubic millimeter and to bring about almost complete alleviation of the neural disturbances, he has received not over 12 injections per year at \$1.20 each or less than \$15.00 a year. Even allowing for the extra cost of a nurse, or even of a physician to give the injection, the expense is still minimal.

It is not logical of course to contrast the treatment received by two individual patients, for each patient's needs vary, depending upon several circumstances. As I have previously reported, however, the average patient in our blood clinic requires only 1 injection of either 1 or 3 cc. of concentrated solution of extract every three or four weeks in order to maintain the blood in a normal state and to produce an optimal state of health. Were the patient to receive the maximal amount of treatment (either 1 or 3 cc. per week), the expense of treatment would be relatively small in contrast to that of daily injections. The difference in the inconvenience to the patient is considerable.

Are we not as physicians, to some extent at least, conservators of our patients' money? Should we not utilize those available means of treatment which will best serve the needs of the patient and which will accomplish the desired result with a minimum of expense and inconvenience to the patient? The surgeon no longer sprays the operating room with carbolic acid in order to avoid wound infection, and the cardiologist is no longer content to treat his patient with hit-or-miss dosages of digitalis of low or unknown potency. Is not the patient with an anemia readily controlled by the anti-

anemia factor contained in liver entitled to treatment by means of the most modern therapeutic measures available?

Although the introduction of a liver extract so prepared as to be of practical value for parenteral injection was heralded as a definite improvement over the use of liver substance perorally, the development of the means of preparing more concentrated extracts for intramuscular injection without appreciable loss of potency and without those irritating substances so characteristic of the less carefully refined material is, particularly for the patient, a most important step in advance. It seemed almost miraculous to be able to produce the striking results observed following the use of a liver extract so concentrated that 3 cc.\* contained the active substance from 100 Gm. of liver. It seems even more remarkable, however, to realize that even further concentration has been accomplished so that one third of this volume or 1 cc.\* contains the active principle from 100 Gm. of liver without loss of potency. The results of the use of this most highly concentrated extract after one and one-half years of experience with it have been reported elsewhere by the author<sup>1</sup> but a brief review of its use in one patient may suffice to indicate the advantages of this modern means of therapy.

Miss F. C., a twenty-seven-year-old salesgirl, entered the hospital on April 9, 1935, with a red blood cell count of 1,000,000 per cubic millimeter. An injection of 4 vials or 4 cc. of a highly concentrated liver extract (Lederle) derived from 400 Gm. of liver, was given the following evening, followed on the morning of the fifth day by a reticulocyte peak of 32.8 per cent. By April 23, the red blood cell count had risen to 3,170,000, a daily increase of 170,000. On April 27 another injection of 1 vial or 1 cc. was given. By May 22, 1935, the red blood cell count had reached a level of 4,550,000 since which time (up to September 29, 1936) she has received 21 injections, each 1 vial or 1 cc., of highly concentrated liver extract intramuscularly.

This patient has therefore received 26 cc. or 26 vials of extract during a period of five hundred and thirty-seven days during which time her red blood cell level has been returned to normal and maintained at an average level of 5,430,000

\* N N R Lederle Laboratories, Inc., Pearl River, N. Y.

cells per cubic millimeter. She has remained steadily at work since May, 1935, returning to the clinic for an injection of 1 cc. of liver extract only at intervals averaging slightly over three weeks. A blood examination has been made at practically each visit in order to insure maintenance of the blood at a normal level.

The need for regulation of the amount of liver substance necessary for the adequate treatment of each patient according to his own requirement has been mentioned. It is difficult to state arbitrarily how frequently a patient's blood should be examined in order to insure its maintenance at a proper level, for this again varies according to certain factors present. Immediately following the reticulocyte rise precipitated by initial treatment, it may be well to examine the blood at each weekly interval that the patient returns for an injection, until a normal or 5,000,000 level has been reached. Examinations thereafter may be made at intervals of one, two or three months, depending upon the state of the blood. If it remains well up to normal, the less frequent intervals may be sufficient. If there is a lag or tendency for the blood level to drop, more frequent examinations will be needed.

The occurrence of an infection or other complication usually is an indication for examination at more frequent intervals than might otherwise be necessary. After the amount of treatment necessary to maintain a normal blood level has been established by treatment for a year or more, examinations of the blood levels may be made only once during four to six months, providing no complication occurs during this time. In no case is it sufficient to test only the hemoglobin level during the course of maintenance treatment because in pernicious anemia this may not satisfactorily indicate the condition of the blood. It is best to follow both hemoglobin and red blood cell levels and certainly the latter. If the level of the red blood cells is not compatible with the clinical state of the patient, an examination of the stained blood film will allow one to decide whether or not the technician has counted the cells correctly.

This is illustrated by the case of a patient, Mr. A. M., who was referred to me for consultation. Mr. A. M. had begun treatment at a time when there was evidence of neural damage which resulted in moderate locomotor difficulty. This condition improved with treatment, but at the end of a year there was again evidence of progression in spite of the fact that sufficient liver was being taken to maintain a count reported to be around 5,000,000. In my laboratory, however, the red blood cell level was found to be only 3,500,000. Which count was correct? An examination of the stained film showed the presence of many oval macrocytes with a tendency to increased size of the cells (confirmed by determination of the individual cell volume) and also many pear-shaped cells, a picture hardly compatible with a normal count. More intensive treatment was instituted, and as the blood returned to normal the neural disturbances again decreased.

The red blood cells, in the presence of a normal level even in a patient with pernicious anemia, should be normal both as to their appearance in a stained film and as to individual cell volume as determined by the hematocrit method.

#### PROGNOSIS

A question frequently asked by one's patient is, "How long must I continue to take liver in some form in order to remain well?" The answer is, that in the light of our present knowledge of the disease, treatment should be continued throughout life. This answer usually provokes the second question, "How long may I expect to live providing treatment is continued?" The answer to this seems to be equally well established on the basis of our experience with treatment during a period of over ten years. In so far as the pernicious anemia is concerned, one should expect to live at least as long as the average individual of his own age. In other words a satisfactorily treated patient should not die from circumstances associated with pernicious anemia but rather from some totally independent illness. Of course it must be realized that many complicating illnesses are of such a nature that it may become increasingly difficult or even impossible entirely to control the pernicious anemia so that the terminal illness may include difficulties related to that disease.

The following cases are illustrative of typical experiences in respect to life expectancy.

Mrs. R. G., a housewife, was first diagnosed as having pernicious anemia in the fall of 1921, at the age of forty-five. Transfusions were effective in maintaining life through three relapses until the early spring of 1925, when liver treatment was begun. Treatment has been continued rather satisfactorily up to the present time and the patient remains in excellent health at the age of sixty-one. According to figures published by the Metropolitan Life Insurance Company<sup>2</sup> the expectation of life at birth from 1911 to 1935, the last report available, was fifty-nine and nineteen one-hundredths years. Their figures also show an expectation of life of twenty-four years for a white female forty-five years of age in 1921. One may therefore expect this patient to live to be sixty-nine years of age. The prognosis is excellent.

Mrs. J. G., a widow, has been observed in the out-patient clinic from time to time because of various ailments since 1915. Up until the spring of 1926, when a diagnosis of pernicious anemia was made at the age of sixty-five, none of these was of such a nature as to suggest this diagnosis. Since 1926, when liver treatment was started, hypertension gradually developed during the first two or three years and four years ago when the patient was seventy-one years of age diabetes mellitus appeared acutely. From the time the diagnosis was made until the spring of 1931, treatment consisted either of whole cooked liver or peroral extract. Since that time intramuscular injections have been used. In spite of the complications noted, this patient at the age of seventy-five remains in a fair state of health with a normal red blood cell count. Again using the Metropolitan Life Insurance Company's<sup>2</sup> expectation of life figures one might expect this patient to live eleven and seventy-five one-hundredths years after the age of sixty-five or approximately to the age of seventy-seven. Certainly one could hardly expect a longer life for an individual with hypertension and diabetes alone.

By far the greater number of persons show evidence of pernicious anemia between the ages of fifty and seventy years than at any other age. The exceptions to this rule, however, are interesting. One patient now being followed in the clinic at the age of eighty-five had nothing in her history or symptomatology to suggest a diagnosis of pernicious anemia until after her eightieth birthday. She is still in excellent health. In several instances the onset of the illness occurred before the age of twenty. I have just had occasion to study a girl, thirteen years of age, who presents a typical blood picture of pernicious anemia, has complained of intermittent, fairly long intervals of sore tongue, has achlorhydria even after the use of histamine, and whose blood response to intramuscular injections of liver extract has been excellent. A negative family history, absence of enlargement of the spleen and

normal fragility of the red blood cells make a diagnosis of hemolytic ictero-anemia highly improbable.

In view of the accumulating number of patients with experiences similar to the typical ones presented, it is obvious that the life span of the pernicious anemia patient may be lengthened by at least ten years (except of course in the older age groups in which the life expectancy of the normal is less), and by continuance of careful control and advice, the life span need not be limited by disturbances directly credited to pernicious anemia.

Although the prognosis, so far as expectation of life is concerned, in a patient with uncomplicated pernicious anemia, may be considered to be excellent, maintenance in a state of economic efficiency for the duration of life is to be considered of almost, if not quite, equal importance. Perhaps the greatest difficulty encountered in this respect is the occurrence of disability resulting from sclerosis of the spinal cord. According to data recently reported by the author<sup>3</sup> concerning the complications occurring in 440 cases, 270, or 61 per cent, presented signs or symptoms indicating some degree of sclerosis. Only 151 had evidence of lateral column involvement, while 42 had evidences of severe locomotor difficulty. Little need be said here in regard to the value of liver therapy in preventing and improving these disturbances inasmuch as this subject has been discussed in many reports. An excellent review of the literature on this subject has recently been presented by Schaller and Newman.<sup>4</sup>

From the evidence now available, certain facts concerning the disturbances associated with neural sclerosis seem to be well established, and it may be desirable to mention them here.

In order to prevent progression of these disturbances to such an extent that the patient will be permanently handicapped in respect to locomotion, it is important to start intensive liver treatment early and to continue an adequate dosage to maintain the red blood cell count at a high normal level. If this is not done and destruction of the nerves is

allowed to continue for a period of months or years, considerable improvement is not to be expected.

If the blood is maintained in a normal state (5,000,000 or more cells per cubic millimeter), disturbances resulting from neural sclerosis do not appear. If they are present when treatment is started, they do not progress, and improvement occurs. The amount of improvement will depend upon several circumstances but primarily upon the amount of nerve damage present at the time adequate therapy is instituted, which in turn usually is dependent upon the length of time that elapses before satisfactory treatment is established.

Satisfactory results will be obtained with maintenance of the blood in a normal state regardless of the method of administration of liver therapy. As this is most readily accomplished by means of parenteral therapy, this method is considered the one of choice.

The institution of exercises designed to retrain the muscles paralyzed and to improve the balance of the patient may favor more rapid and complete recovery of the function of locomotion.

So many excellent, almost miraculous, results have been observed in patients exhibiting marked locomotor difficulties that it is very difficult to choose one or two of the most interesting to present. On the other hand, the failures have been so unusual that the following case may best illustrate the points emphasized above.

Mr. J. O., a forty-five-year-old war veteran, presented himself for treatment with a red blood cell count of 900,000. He was unable to walk or to stand without aid. This patient had been treated in a veterans' hospital during a two-year period, usually with a moderate dose of a council-accepted liver powder. Locomotor difficulties had been present during this period, and in spite of some liver therapy the red blood cell level had not only remained subnormal but also had actually dropped to the low level recorded. Of course the result was progression of the cord difficulty to the worst possible state. With intensive treatment by means of intramuscular injections it has been possible to maintain the blood in a satisfactory state, and locomotion has been slightly improved. Further improvement probably cannot be obtained because of the degree of damage present. As a result of inadequate therapy this patient will be unable to become an economically efficient member of society. Had he re-

ceived earlier the benefit of adequate treatment, so readily available, this tragedy need not have occurred.

The cases of the 2 following patients illustrate the bright side of the problem; in the second instance even in spite of rather prolonged inadequate therapy.

Mrs. A. D., a thirty-eight-year-old housewife, began treatment in January of 1932 with intramuscular injections of a concentrated solution of liver extract. At this time she was confined to bed and was unable to walk because of locomotor disturbances resulting from spinal cord sclerosis. The red blood cell level was then 2,000,000 cells per cubic millimeter, hardly low enough to increase the locomotor difficulty because of weakness. As treatment brought the blood levels back to normal and exercises designed to retrain the paralyzed muscles were carried on, locomotion improved. At first it was necessary to lift her into and out of an automobile and to a wheelchair in order to get her to the clinic for treatment. Within three months she was able to walk alone, and today she is a picture of health and has no evidence of locomotor disturbance.

The diagnosis in this patient was made and intensive treatment begun early in the course of the disease before the spinal cord damage had advanced to an irreparable stage. Under such circumstances even those evidences of pernicious anemia, which may prove to be serious handicaps to economic efficiency, are readily controlled.

. In January of 1932, Miss R. O., previously mentioned, a forty-five-year-old school teacher, whose illness began rather insidiously with frequently recurring attacks of diarrhea over a period of several years, followed by a tendency to tire easily and a sore tongue and mouth, presented herself for treatment.

During the early part of her illness several physicians, who were consulted, failed to make a diagnosis, but on the advice of one of them, a year's leave of absence was taken to travel and rest. While traveling fatigue became more and more intense, the diarrhea increased, and evidence of cord sclerosis appeared making further travel impossible. She then consulted a medical missionary, the only physician in the vicinity of a small town in India, who made a diagnosis of pernicious anemia and advised liver therapy. Her condition improved sufficiently to allow her to continue her journey. During this time some evidence of locomotor difficulty had appeared, but while at a large "clinic" in the West, it became acutely worse following an "adjustment" of the spine, which was to have "cured" her illness. At this "clinic" a diagnosis of psychasthenia was made, and the possibility of sprue was considered. The liver treatment was stopped. During the ensuing year numerous physicians consulted made varying diagnoses and gave conflicting advice. Through it

all, however, liver treatment was continued irregularly, but it was not of sufficient intensity to bring about any considerable improvement.

She had presented herself for treatment, however, after a period of rather intensive liver therapy, and therefore, her blood was in a fairly satisfactory state although the attacks of diarrhea persisted unless controlled by opiates, and she was unable either to stand or walk unless supported. Intensive intramuscular liver therapy and exercises for the purpose of retraining the paralyzed muscles and improving the balance were started. In spite of the long-standing and progressive locomotor difficulty this patient has been able, after approximately two years of incapacity, to return to her teaching position in an excellent state of health and without sufficient locomotor difficulty to be recognizable by one not familiar with her condition.

Needless to say such a splendid improvement has not been obtained by a careless, haphazard observance of the treatment instituted, but it is the result of the most meticulous attention to all the details of treatment, especially those necessary for maintenance of the blood in a perfectly normal state, and an indomitable will to return to a normal state of health and to the status of a self-supporting member of society.

What a pleasure it is to supervise the treatment of a patient whose cooperation and desire to recover a normal state of health has been so enthusiastic! The majority of patients with pernicious anemia will be found willing and anxious to cooperate. With sympathetic encouragement and thoughtfully considered advice in respect to the details of treatment of the various problems as they arise, results equally satisfactory may be obtained in virtually all instances.

## CLINIC OF DR. FRANCIS T. HUNTER

IN CONJUNCTION WITH THE X-RAY DEPARTMENT OF THE  
MASSACHUSETTS GENERAL HOSPITAL

### THE LEUKEMIAS: THEIR DIAGNOSIS, PROGNOSIS AND TREATMENT

In sketching for you the diagnosis, prognosis, and treatment of the leukemias, I must ask you to consider not only chronic myelogenous and chronic lymphatic leukemia but also those rarer forms of the same group of diseases, *aleukemic leukemia* (both myelogenous and lymphatic), *pseudoleukemia*, and *acute leukemia*. Since our allotted time is so short, it occurred to me that I might more clearly convey to you the usual course and clinical picture encountered in these conditions by presenting imaginary rather than real patients. I have, therefore, telescoped the more common events and findings into single cases and offer them as samples of what one might expect to meet with in a general practice.

#### CHRONIC MYELOGENOUS LEUKEMIA

Let us, then, consider Mr. A., a man in his late thirties, who comes to us complaining of fatigue and of the presence of a mass in the abdomen. Giving no definite date of onset of his symptoms, he tells us that for the past six to eight months he has felt somewhat unwell, and that three months ago he noted a mass in the left upper quadrant of the abdomen. Although not painful, a sense of pressure and a dull aching in the region of the tumor first drew his attention to it. On closer questioning he admits some loss of weight, increased perspiration, and vague gastric distress. He stoutly denies excessive bleeding or abnormal bruising, and adds that if it

had not been for the insistence of his wife, he would not have consulted a doctor.

When we examine him, we find little to attract our attention excepting a slight pallor, a warm skin, and an enlarged spleen; the latter, on careful palpation, is observed to extend to the level of the iliac crest. On examination of his blood, however, we discover a slight anemia (3,900,000 red corpuscles per cubic millimeter), and a leukocytosis of 150,000 per cubic millimeter. A study of the white cells in the stained smear shows them to consist almost entirely of elements of the polymorphonuclear series at various stages of maturation. The predominant cell is the myelocyte, but we find, in addition, many immature polymorphonuclears, a few myeloblasts, and an occasional nucleated red cell. The red cells themselves show only slight changes in size and shape and seem to be fairly well filled with hemoglobin. We decide that the platelets are somewhat increased in number. Moreover, on two consecutive determinations the basal metabolism rate is elevated above plus 40 per cent.

As the diagnosis is obvious, we inform the patient's wife of the situation and tell Mr. A. himself that he has a disease which is quite susceptible to x-ray therapy, but that treatment will have to be repeated from time to time. Consequently, after a day or so on a diet high in carbohydrates and sugar in order to prevent roentgen sickness (a possibility, by the way, which should never be mentioned to the patient), our radiologist administers 200 r at 200 K.V. peak through a 15 × 15 cm. lateral portal to the spleen. As this dose is well tolerated, similar treatments are given on successive days until a total dosage of 600 r is reached. Upon completion of his course of therapy Mr. A. goes home and is told he may do anything he feels like doing. No medicine is prescribed.

Eight weeks later our patient comes back for observation. proud of having gained 10 pounds, and feeling better than he has in several years. The spleen now extends only to the costal margin; the white count is 20,000 per cubic millimeter. A few myelocytes are still present in the smear, but aside from

this, the blood looks fairly normal. Since there is no immediate need for further roentgen therapy, we advise him to resume his normal activities and to return later for examination.

During the next few months Mr. A. reports at intervals of six to eight weeks. We note at each visit a gradually rising white count, an increasing immaturity of the leukocytes, and a slowly enlarging spleen, but since he feels perfectly well, treatment is withheld. About the sixth or seventh month after the completion of the first series of treatments, however, the white count has again reached 75,000 per cubic millimeter, and from past experience we know that the old symptoms of fatigue and sweating will shortly make their appearance. Therefore, another course of therapy similar to the first is advised and administered—its effect on the spleen and white count being essentially the same as that produced by the first course.

For the next two years Mr. A. continues to work, enjoys golf, and feels in every way normal, with the exception that on one or two occasions he states he has suffered for several days from a "pleuritic" pain in the left lower chest and a nagging dull ache in the left shoulder. (Symptoms such as these are obviously produced by infarcts of the spleen and have no great significance.) Nevertheless, as time goes on, we observe that the results of radiation are less marked; after treatment the spleen does not diminish in size as it did in the earlier phases of the disease, the white count rises more rapidly, and treatments must be given with greater frequency.

In the latter part of the third year of his illness, we find the effect of radiation lasts a scant two months. Within a short time an abrupt change takes place in his condition. An occasional purpuric spot appears on the legs; fatigue and exhaustion become prominent symptoms; splenic pain troubles him; a slight fever is detected from time to time. The spleen, now at the level of the umbilicus, no longer regresses with treatment: the red corpuscle count gradually declines to a level of 3,000,000 per cubic millimeter; the white count re-

mains elevated at the 50,000 level or above and resists farther reduction; myeloblasts appear in greater numbers in the stained smear, and the platelets become scarcer. Therapy no longer produces clinical or hematological improvement. Three weeks or so after the final treatment, Mr. A. takes to his bed. He now shows considerable emaciation; purpuric spots crop out on the arms, legs, and trunk, some oozing of blood occurs from the gums; a small area of gangrene appears in the mouth; scattered râles may be heard at the bases of the lungs; and, finally, a continuous low-grade fever and a rapid pulse herald the end. His wife inquires about blood transfusion, but we inform her that it would not only do no good but might make her husband more uncomfortable. Thus, approximately three years from the beginning of his first symptoms, after a period of four or five weeks in bed, our patient finally succumbs to his illness.

The foregoing description depicts the ordinary course and usual findings in an uncomplicated case of chronic myelogenous leukemia. Lack of time forbids a full description of all its possible clinical manifestations, but brief mention of certain ones might be made. In some instances the course is either shorter or longer than the one given here. For example, one of our patients has been known to have had the malady for at least eighteen years, and, although treated at rare intervals, she is still living and enjoying an active life. At times divergence from the classical blood picture is encountered. We have now under observation two examples of the disease accompanied by polycythemia, each with red cell counts above 7,000,000 per cubic millimeter. Similarly, variations in the physical findings occur at different stages of the malady. Some patients develop leukemic retinitis, others failing hearts; some may show no purpuric manifestations before death. others, on rare occasions, may exhibit infiltrations of the neoplastic tissue into the skin. And finally, while in our experience ascites is not infrequently a terminal event, priapism—so frequently mentioned in the textbooks—we have observed only once.

In summary, the diagnosis offers no difficulties, the prognosis for at least two years of comfortable life is excellent, and, although arsenic in the form of Fowler's solution is recommended by some, in our opinion high voltage x-ray therapy as often as may be indicated in each individual case is the therapy of choice.

#### ALEUKEMIC MYELOGENOUS LEUKEMIA

A woman, let us say in her early fifties, enters the hospital for study. The diagnosis of pernicious anemia has been made, but she has failed to respond to adequate doses of liver. Her story is one of several months' weakness, exhaustion, dyspnea, palpitation and increasing pallor. Perchance she may have had short periods of fever. No other significant information is obtained either from her or from her anxious family. When we examine her, we note the marked pallor, the presence of a few petechiae on the shins, and a spleen palpable possibly 6 to 8 cm. below the costal margin.

Examination of the blood reveals a puzzling picture. The white count is 4000 per cubic millimeter, the red blood corpuscles 2,500,000 per cubic millimeter, and the hemoglobin 60 per cent—a color index sufficiently high to justify a suspicion of pernicious anemia. A stained smear, however, shows certain unusual features. As in pernicious anemia, the red cells are on the average somewhat larger than normal, are well filled with hemoglobin, and exhibit considerable variation in size and shape, but the platelets are definitely fewer in number than we should expect in that disease. Moreover, the polynuclear cells, instead of showing aged forms (5 or 6 lobes), are, on the whole, quite young; a few myelocytes are present, and careful search may disclose an occasional myeloblast. We suspect aleukemic myelogenous leukemia and feel more certain of that diagnosis when the basal metabolic rate is found to be plus 40 per cent.

In order to settle this important question, that of a disease with a fatal prognosis, a surgical colleague performs a biopsy on the sternal marrow; and when the pathologist re-

ports "myelogenous leukemia," or "aleukemic myelosis," our diagnosis, suspected from the examination of the blood smear, is verified. In retrospect, we recall that the spleen seemed too large and the petechiae somewhat unusual for pernicious anemia, but admit that the diagnosis could not have been made with any certainty without the evidence obtained from the biopsy specimen.

In contrast to the classical type, in this form of the disease the prognosis and indications for treatment are by no means obvious. Length of life varies from a few months to one or two years, and on occasion a patient may live five or six years. In general, however, aleukemic myelogenous leukemia has a shorter course than the leukemic form of the disease; but, so far as I know, there are no signs which enable one to predict with any degree of accuracy how a particular patient will behave. Treatment, too, is more difficult to plan. Seldom producing brilliant results, high voltage x-ray therapy to the spleen, nevertheless, is always worthy of trial. More often than not it is injurious, at times producing a greater degree of anemia, or even enhancing the purpuric tendencies, but the same undesirable results may also be seen after blood transfusions. There is a possibility that "spray irradiation" of the whole body may prove of value in certain cases; at the present time, however, this type of x-ray therapy has not yet been adequately investigated. We can only conclude, then, that each case of the disease requires individual handling. The most important fact for the medical attendant to remember, particularly when faced by insistent relatives, is that it is incumbent upon him to avoid making his patient worse by ill-considered therapeutics.

#### CHRONIC LYMPHATIC LEUKEMIA

Miss H., a spinster, possibly forty-two years of age, comes to us because of the presence of enlarged glands in the neck and groins. She admits these tumors first appeared about a year ago, but since they were nontender, painless, and stationary in size, Miss H. did not consult a doctor. During the

past four months, however, a loss of 5 pounds in weight, increased fatigability, gradual enlargement of the glands, and disturbing comments of friends finally induced her to seek medical advice. A more detailed inquiry into her medical history fails to account for these swellings, and adds no facts of importance.

Upon examination, our patient, in addition to showing moderate pallor, exhibits enlargement of the glands on both sides of the neck, in each axilla, and in each groin. In each site they range from 6 to 10 in number, and vary in size from 1 to 4 cm. Their consistency is firm, elastic rather than hard, and they move freely beneath the skin. An enlargement of the spleen is present, this organ projecting 6 cm. below the costal margin.

Examination of the blood reveals a red corpuscle count of 3,500,000 per cubic millimeter, the hemoglobin is 60 per cent, and the white cell count 100,000 per cubic millimeter. A stained smear shows that 90 per cent of the white cells are small lymphocytes, relatively normal in appearance. The red cells exhibit moderate variations in size and shape; the platelets are somewhat diminished in numbers.

With the diagnosis of chronic lymphatic leukemia thus established, we repeat to Miss H. what we said to the patient with chronic myelogenous leukemia, and plan our high voltage x-ray therapy as follows: 600 r through adequately sized fields (ordinarily  $10 \times 10$  cm.) to each group of glands in the neck, axillae, and groins, and the same amount, through a larger field ( $15 \times 15$  cm.), to the spleen. Under ordinary circumstances this amount of irradiation will bring about marked regression in the size of the tumors, and will reduce the white count to less than 25,000 per cubic millimeter. Occasionally certain sites will require more therapy than here outlined; usually, however, they may be further treated with safety, since the effect of roentgen therapy on the white count in this disease is not so marked as in the myelogenous type.

After the initial course of treatment, the patient returns for observation at intervals which vary in length according to the

circumstances of the case. But since in this disease the blood is not the sensitive indicator of the need for therapy that it is in myelogenous leukemia, decision in regard to treatment must be based on other findings. Because some patients feel well with a leukocytosis of 75,000 per cubic millimeter, others miserable at a level of 20,000, the general feelings of the individual in conjunction with the complete physical findings are of more importance than the condition of the blood. In some instances sarcomatous infiltration takes place into the skin, subcutaneous tissues, bones, nervous system, conjunctivae, tonsils, pleurae, stomach, liver (with jaundice), kidneys, prostate, or testes. Regardless of the site, such abnormal tissue should be adequately irradiated. The dermic form of the disease, *mycosis fungoides*, which is merely a lymphoblastomatous neoplasm first manifesting itself in the skin, frequently exhibits a leukemic blood picture in its later phases, and as such, should be treated as an ordinary case of lymphatic leukemia. Obviously, then, there are no hard and fast rules applicable to every case. Each must be regarded as a separate problem.

The length of life from the onset of the first symptom varies remarkably from one case to the next. As a general rule, the disease seems more *benign* in patients over sixty-five than in those under forty-five. In this clinic we have observed patients who have lived only six months, others who have lived nine to ten years. Yet, you must be warned that a prognosis derived from the first clinical impression is not always correct. As an example of this, the following instance comes to mind. Two years ago, a patient, apparently moribund, whose symptoms had appeared only eight weeks previously, was given unusually heavy irradiation through large fields to the chest and abdomen despite the fact that he showed ascites, general anasarca, and pulmonary edema. Three months later, he had recovered sufficiently from his malady to go on his annual duck shooting expedition. At the present time he is still living and carrying on his business.

## ALEUKEMIA AND PSEUDOLEUKEMIA (LYMPHATIC TYPE)

Since the pathologic histology of all three conditions is the same, the terms *lymphatic leukemia*, *aleukemia*, and *pseudoleukemia* do not define separate diseases, but designate clinical variations of a single morbid process. The qualifying term *aleukemia* has been applied to those cases with normal or subnormal total white counts that have a lymphocytosis above 60 per cent; *pseudoleukemia*, to cases that show no definite evidence in the peripheral blood of the neoplastic process going on in the lymph glands and spleen. That all of these conditions are phases of lymphatic leukemia is illustrated by one of our former patients, who, during seven years' observation, passed from the leukemic, through the aleukemic, and into the pseudoleukemic phase in which he died. Preferably, we should employed Mallory's designation of "lymphoblastoma" to include all tumors arising from the lymphocyte, and should add to it the necessary clinical qualification, *e. g.*, "lymphoblastoma aleukemicum."

As we have seen, lymphatic leukemia is readily diagnosed from the blood examination alone. Usually in the aleukemic phase, the peripheral blood enables us to be certain of the diagnosis, but on occasion a biopsy is necessary. In the pseudoleukemic phase, however, a biopsy of a lymph gland is always required if we are to have our clinical impression confirmed.

Neither the course, prognosis, nor treatment of these two phases of the disease differs essentially from that of lymphatic leukemia. If anything, when we contrast either one with lymphatic leukemia itself, we are apt to find its course more bizarre, its prognosis more unpredictable, and its treatment more perplexing.

## ACUTE (MYELOBLASTIC) LEUKEMIA

We are called to see a boy eight years of age, who has been in bed for the past ten days suffering from weakness and fever. From the information at our disposal we obtain the following noteworthy facts: approximately four weeks ago,

the lad was put to bed by his mother for what seemed to be an ordinary attack of grippe. After a few days of malaise and fever, however, he recovered sufficiently to return to school. Soon thereafter, the mother noticed his lack of appetite and his unusual weariness, but she only became alarmed ten days ago when she realized how pale he had become. Upon finding a temperature of  $101^{\circ}$  F., the child was again put to bed, and since that time he has continuously shown a fever, his appetite has rapidly failed, and his pallor has become even more marked. Aside from a few bruises recently noted on the skin, the rest of the story gives us no essential facts.

On physical examination, our patient looks moderately ill, is quite pale, and shows a temperature ranging from  $99^{\circ}$  to  $101.5^{\circ}$  F. We observe a moderate number of petechiae on the skin of the limbs and trunk, several similar lesions on the mucous membrane of the mouth, and a few small bruises scattered over the legs and abdomen. With the ophthalmoscope we make out a few small hemorrhages into the retinae. On palpating the neck, axillae and groins, we note the glands in each of these regions are somewhat enlarged, the majority averaging 1 cm. in size. Examination of the abdomen shows the liver and spleen to be enlarged, the latter being palpable 4 cm. below the costal margin.

Our worst forebodings are confirmed by the examination of the blood. There is an anemia of 2,500,000 red blood corpuscles per cubic millimeter, and the white cell count is 70,000 per cubic millimeter. In the stained coverslip preparation, all of the white cells appear to be either myeloblasts or primordial cells too immature for classification, a few nucleated red cells are noted, and the platelets are practically absent. Yet, in spite of this grave disturbance of bone marrow function, the mature red cells seem to be fairly normal in size and shape. As one would expect with so few platelets, the bleeding time is strikingly prolonged. Hoping for the remote possibility that the disease might be an unusual manifestation of *infectious mononucleosis*, we send a specimen of serum to the nearest Wassermann laboratory for determination of the

heterophile antibody titer. (In infectious mononucleosis this is usually as high as 3 plus in a dilution of 1:64.) But in a day or so, the report returns marked "negative."

At this point someone is certain to raise the question of "acute monocytic leukemia." For all practical purposes, however, this is an instance of academic hairsplitting. Whether or not such a separate disease exists need not concern us, for the prognosis and treatment are no different than if the diagnosis be myeloblastic leukemia.

The prognosis in this terrible malady is not difficult to make. From the onset of symptoms the length of life is usually six weeks; occasionally a patient may live eight to ten weeks, but rarely longer. Few diseases in the field of medicine have a 100 per cent fatality such as this, and fewer still have such a sharply defined course. Toward the end, the anemia becomes more marked, the purpuric tendency more manifest, and often there occurs gangrene of the buccal cavity. The white count frequently becomes lower, and on occasion the terminal blood picture may simulate agranulocytosis.

All specific treatment is futile. x-Ray therapy practically always makes the patient worse. The use of blood transfusions and arsenic preparations is to be discouraged, for neither agent produces with any consistency even temporary benefit. Obviously, then, when faced with a situation of this sort, the medical attendant should try to make the patient as comfortable as possible, and should do all in his power to convince the family of the importance of doing nothing. The first is solved by employing a good nurse, the second by utilizing the services of consultants.

### NOTES ON THE TREATMENT AND PROGNOSIS OF HODGKIN'S DISEASE AND ALLIED DISORDERS

OUR present-day treatment of Hodgkin's disease is admittedly inadequate, yet we must acknowledge that dramatic remissions, often of long duration, may be brought about even with the limited therapeutic measures at our disposal. The prognosis is conceded to be grave, yet it is undoubtedly true, in certain instances at least, that the disease runs a benign and chronic course of many years' duration. We must not allow our pessimism to prevent persistent and relentless treatment even in the face of apparently hopeless odds. Many patients who appear to be well nigh moribund may, by appropriate measures, be restored to some degree of health and in rare instances, though the diagnosis appears, from biopsy, to be certain, the patient may live for many years undisturbed by the underlying condition.

The following cases serve to illustrate this thesis.

Case I.—K. A. D., a twenty-year-old white, single man was admitted to the hospital May 25, 1936 (H. H. 36-542.) A year before entry the patient had had a mild upper respiratory infection following which there had appeared an enlarged lymph node in the right neck. There was no impairment of general health. The node was neither painful, red nor hot yet it persisted after subsidence of the respiratory infection. Eight months later his family noticed that the patient was becoming pale. For several weeks before admission, he had been running a septic type of temperature and had had many rather

severe, drenching night sweats. Shortly thereafter there appeared edema of the ankles and scrotum and, coincidentally, both his hearing and vision began to fail. He had several severe nosebleeds.

The past and family history were irrelevant.

Physical examination, on admission to the hospital, showed a poorly nourished, emaciated, young man lying apathetically in bed. He appeared to be in extremis. His vision was markedly impaired. General objects he could distinguish but even the largest newspaper type could not be read. The left pupil was much larger than the right. Both reacted well to light and distance. The left eye showed a moderate degree of enophthalmos and was deviated downward and inward. The right fundus showed several patches of exudate similar to that seen in chronic nephritis and, in addition, a large area of chorioretinitis on the temporal side of the disk. The left fundus showed a high degree of optic atrophy. In neither ear could he hear the tick of a watch. Both nostrils were filled with clotted blood and his lips were parched, cracked and bleeding. In the right neck, from the angle of the jaw to the supraclavicular space, were many firm, nonadherent lymph nodes averaging about 2 cm. in diameter. Recently, there had been excised from this region a lymph node, the examination of which showed the typical picture of the sclerosing type of Hodgkin's disease. In each groin were large numbers of firm, tender lymph nodes. Many similar nodes could be felt deep in the pelvis, above the pelvic brim. The heart was normal in size. Signs of moderate ascites were present, but neither liver nor spleen could be felt. There was marked edema of both legs and of the scrotum and penis. The red blood cell count was 2,130,000 per cubic millimeter; the hemoglobin 30 per cent; the white blood cell count was 2000 per cubic millimeter; the platelets were greatly diminished. The differential white blood cell count was normal. The urine contained a small trace of albumin and a few red blood cells. The temperature was 103° F. The pulse 130.

The disease obviously involved the central nervous system, ears, eyes, chest, abdomen, pelvis, bone marrow and peripheral lymph nodes. It would be difficult to find an instance of more widespread involvement. Rarely does one see a patient in more dire straits. His condition seemed, indeed, desperate and it was decided to give several blood transfusions before instituting x-ray therapy. In addition, he was put on a liberal, high caloric diet and given 3 drops of a special viosterol containing 1,000,000 international units per cubic centimeter.

Between May 26th and June 11th, three blood transfusions, totaling 1600 cc., were given with the result that the hemoglobin rose to 50 per cent and his red blood count to 3,500,000 per cubic millimeter. During the interval his general condition remained essentially unaltered, but, interestingly enough, his hearing improved sufficiently so that he could hear a watch tick in either ear and could understand normal conversation. His eyesight had similarly improved though not to the same extent. His condition now appeared to warrant the institution of x-ray therapy and inasmuch as the most marked lymph node involvement was in the pelvis, radiation was directed to that area and from June 11th to June 15th, he received 275 r units of high voltage x-ray. He suffered no untoward reaction to this small amount of radiation so that

between June 15th and June 22nd he was given 1000 r. units to the abdomen. His temperature remained elevated, the physical examination was essentially unaltered and his general condition seemed, if anything, rather worse. He became jaundiced and, even during the day, he was somewhat drowsy. He took no notice of his surroundings and was, with some difficulty, aroused from his almost constant lethargy. The red blood cell count had fallen to 1,940,000 per cubic millimeter and the hemoglobin to 32 per cent.

The outlook was certainly not bright; all therapeutic measures to date appeared to have been unavailing. In view of the falling red blood cell count he was given, between July 1st and July 10th, 2000 cc. of blood intravenously with a resultant rise of the red blood cell count to 3,480,000 per cubic millimeter. By this time his temperature had come down to normal, his hearing was perfect and his eyesight, though still poor, was much improved. He was allowed up and around the ward within the limits of his strength. His appetite, on admission practically nil, was now ravenous. His general condition improved daily. He rapidly gained both strength and weight. The emaciated, apathetic boy first seen became an optimistic young man. The lymph nodes in all areas became very much smaller. The ocular manifestations improved with the exception of the retinal changes which remained unaltered. The peripheral edema and ascites had disappeared. On July 20th he was given another blood transfusion of 500 cc. and on July 25th he walked out of the hospital to return to his home.

There would seem to be no question but that the many blood transfusions—a total of 4000 cc.—played a major rôle in this patient's recovery and it has been our general experience, especially in patients running high temperatures, that transfusions are highly beneficial. The influence of the viosterol is, of course, problematical, but it has been our feeling that it is helpful. Radiation must, of course, be used but blood transfusions and other general therapeutic measures are important adjuvants.

Case II.—J. A., a nine-year-old boy was admitted to the hospital August 22, 1935 (H H 35-931.) One year before entry there had appeared enlarged lymph nodes behind the left ear. For six months he had suffered from weakness and anorexia. Four months before entry more lymph nodes had appeared on the right neck and these had gradually increased in both size and number. For the past six weeks he had been running a temperature ranging up to 104° F. and had suffered from vertigo, headache and rapidly increasing pallor. On admission he was found to have a temperature of 105° F. He was very weak, trembling and sweating profusely. The skin and mucous membranes were extremely pale. In the right cervical region were many firm lymph nodes from 1 to 3 cm in diameter. The lungs were clear. The heart was normal in size. The apex beat, however, was very forceful and diffuse. The cardiac rate was

His temperature once more abruptly receded and he was discharged well, active and without abnormal findings on July 27th.

There again we have an excellent example of what transfusions plus repeated radiation can accomplish. In September he was desperately ill, anemic, jaundiced, edematous, with an enormously enlarged heart, a spleen below the umbilicus and a temperature of  $104^{\circ}$  F. A year later his physical examination was entirely normal and he was able to participate in all the normal activities of his age.

The average duration of Hodgkin's disease is probably in the region of three years; but the outside limits are extreme. Many cases, particularly of the sarcomatous type, die within a few months from the onset of their symptoms, but on the other hand, a few cases survive many years, some with, some without, signs of the disease. When a case may be said to be cured is a matter of debate. Some authorities believe that all cases eventually succumb to the disease. An osteogenic sarcoma, surviving amputation and free from all signs of recurrence three years later, may properly be said to have been cured. Hodgkin's disease, on the other hand, may lie dormant for many years, only to flare up and run a rapid course to a fatal termination in a few months. In other instances, however, the disease early appears to be restricted rather sharply to a certain area and this fact, together with the knowledge that certain pathological types appear to run a benign course, justifies the hope, at least, that if the condition be attacked early and with vigor, a cure may be effected. The following cases of Hodgkin's disease or reticulum-cell sarcoma—a disorder probably closely allied and clinically often indistinguishable—illustrate this point.

Case III.—T. H., a seventeen-year-old boy, was admitted to the hospital on August 20th, 1920. (S-20-1522.)

Five years before entrance he had noticed small, painless lymph nodes in the right neck above the clavicle. These had gradually grown in size and in number to the time of his admission to the hospital. His past history was uneventful. There were no symptoms referable to the enlarged nodes. Physical examination, on entrance, showed no abnormalities except in the right neck

Here was found an enormous mass of firm, nonadherent, nontender lymph nodes, the whole mass approximating the size of a grapefruit.

On August 22, 1920 the mass was completely excised. All involved nodes appeared to have been accessible and were removed. Examination of these lymph nodes showed the typical picture of Hodgkin's disease. (S-20-1522.) The patient was unfortunately told by one of his friends that he would die in six months. As a respite from this gloomy outlook he had recourse to hard liquor in large quantities. At the end of a year he found himself noticeably alive but unable to forego his alcohol. To date, October, 1936, sixteen years later, he has had no signs of recurrence even though examined repeatedly and carefully, but he has had but scant success in combating the alcoholism. He may, I believe, be regarded as cured.

Case IV.—L. C., a thirty-six-year-old woman, was admitted to the hospital in April, 1936 (Lo. Cl. 1936). In 1910, at the age of thirteen years, enlarged lymph nodes had appeared in the right neck. These had been removed at another hospital and had been diagnosed as Hodgkin's disease. The sections have but recently been reviewed by the pathologist and by ourselves and there can be no question but that the diagnosis is correct. She remained entirely well until 1917 when the lymph nodes recurred. Again they were removed and again (S-17-367) they showed the typical picture of Hodgkin's disease. No further signs or symptoms occurred until two months prior to her last admission, when, once more, the lymph nodes appeared in the right neck. Physical examination revealed no abnormalities except that in the right neck beneath the upper third of the sternomastoid were a group of firm, freely movable nodes. These were excised again and showed (S-36-1256) the picture of Hodgkin's disease.

For twenty-six years she has harbored the condition known as Hodgkin's disease, yet she still remains in excellent general health.

Case V.—W. J. B., a forty-four-year-old white man, was admitted to the hospital, October 8, 1924 (M. G. H. 265742). Ten months before admission he had noticed some pain at the lower end of his right humerus. He was treated with ultraviolet light by his personal physician with much relief. Five months before admission, while throwing a baseball, he experienced a sharp, stabbing pain in his right arm and found himself unable to flex his arm at the elbow. A *Rays* showed a fracture but there was evidence of tumor. He was, therefore, treated conservatively and he recovered, to some extent, the use of his arm. In August, 1924, five months later, it was noted that the fracture was unhealed but it was not until October that an x-ray diagnosis of malignancy was finally possible, and on October 9, 1924, the right arm was removed at the shoulder by Dr. C. C. Simmons to whom I am indebted for this case report. The entire humerus was virtually destroyed by tumor from one end to another. The sections showed typical reticulum-cell sarcoma (S-24-10-56).

The patient remained well until October, 1931—seven years later—when

there was a recurrence in the skin near the point of amputation. This was widely excised and the patient is, to date (October, 1936), alive and well without any signs or symptoms of recurrence, twelve years after the amputation. In view of the extraordinary degree of involvement of the humerus and the comparatively long delay between the first symptom and the amputation, the result must be regarded as extraordinarily good and would further, it seems to us, argue for the occasional, isolated nature of the disease. It is difficult to believe that with such extensive disease the patient could be alive and free from signs and symptoms twelve years later had the pathological process originally been, in reality, widely disseminated.

These examples could be multiplied several fold and it would be well to bear them in mind in considering the choice of treatment in a given case. That in the vast majority of instances of Hodgkin's disease, reticulum-cell sarcoma and lymphosarcoma, the process, when first seen by the physician, has involved more than one area of the body, is not to be denied, but that in some, at least, the disease may start from, and be limited to, a given focus, is indicated by such instances as are referred to above. It is unfortunate that by the means now at our disposal the pathological changes cannot be more surely detected in their early stages. In the majority of instances Hodgkin's disease is, at onset, painless—as are many cases of reticulum-cell sarcoma. Were osteogenic sarcoma essentially a painless disease the number of true cures would be vanishingly small. Were Hodgkin's disease, essentially and in its early stages, painful, the number of true cures would, unquestionably, be greater.

**Summary.**—*x*-Ray therapy probably does not, on the average, materially prolong life in Hodgkin's disease, but persistent treatment, especially when combined with blood transfusions and viosterol in large amount, can produce marked and lasting benefits even in those patients who appear virtually moribund when first seen by the attending physician.

In certain instances, Hodgkin's disease and reticulum-cell sarcoma would appear to be a localized condition in its early stages. Radical measures, undertaken early, offer, in these instances, a very real hope of permanent cure.

## CONTRIBUTION BY DR. ROGER I. LEE

BOSTON

---

### A CASE OF POLYCYTHEMIA VERA OR ERYTHREMIA

THIS patient, age fifty-five, presents himself on account of very general symptoms. He cannot tell when his first symptoms began. He thinks it was a matter of years. Apparently, there has been a gradual increase in these symptoms and there has been some punctuation with severe headaches which are increasing. These indefinite symptoms, of which he complains, consist of "feeling tired," "waking up tired," and "going to bed tired."

As you perceive, he is a very intelligent man. He is, by profession, a minister. Despite his rather extensive vocabulary, he cannot further describe his symptoms. He finds it increasingly hard to carry on his profession. He finds physical, nervous and mental efforts equally trying.

He states that all the members of his family, on his father's side, have been full-blooded and very ruddy people. His father and grandfather were both of this same appearance, and this seems to be true of his 3 brothers, although he is the ruddiest of them all. I know casually these brothers and, as a matter of fact, I made blood studies of 2 of them and those studies have been negative. This man, although married, has no children and, curiously enough, two children of one of his ruddy and apparently plethoric brothers are especially pale and pasty.

It is true that complexions, such as ruddiness, amounting, in this case, to an appearance of plethora in the lay sense, have a marked tendency to run in families. The patient volunteers the information that his family, as a family, is sparing of food and drink. He himself is essentially a teetotaler, as

far as alcohol is concerned and, yet, his ruddy complexion would suggest overindulgence in red meat, the ales and wines.

Our patient feels that his correct diagnosis is that he is "full-blooded," and he believes that his headaches are due to too much blood in his head. He has said that he would be better for bleeding and has expressed the wish that he lived in the days when bleeding was a common method of therapy.

There is one other symptom which he finds very distressing and that is priapism which occurs at irregular intervals and is of irregular duration and, moreover, is not relieved by masturbation or intercourse with or without ejaculations.

The essential facts of his physical examination confirm the impression which our eyes give us. The retina is congested. Large and engorged veins can easily be seen. As one scrutinizes the skin of the nose and the mucous membranes of the nose, mouth and throat, one sees this same tendency to engorgement and the presence of easily visible bluish capillaries. The heart is not enlarged. The blood pressure is not particularly elevated. In his case, it is 145/90. The spleen is definitely enlarged and easily felt. There is no edema. Of course, the main interest is in the blood condition. We find his red count to be 11,000,000, his white count 17,500. Hemoglobin reading is high, 120 to 130 per cent in this case, but the color index is under 1. The blood smear shows slight hypochromia. There are normoblasts and megaloblasts present, but the differential count is not significant. The blood platelets are moderately increased. The blood volume in this case, as in all others, is definitely increased. It is about two times normal. The clotting or coagulation time of the blood is slightly delayed. The bleeding time is normal. The resistance of the red cells to the varying strengths of solutions of sodium chloride is so close to normal as to require no comment. His urine is often free from albumin and sometimes contains a small amount of albumin and at times a few casts. There is no fixation of the specific gravity of the urine. The Wassermann test is negative. The blood chemistry is not significant.

The diagnosis in such a typical case presents no real difficulty. There are times when the diagnosis may present a considerable problem. There are the borderline cases in which the elevation of the red count is not so high as in this case, but may be, let us say, between 6,000,000 and 8,000,000 reds. As a matter of fact, our normal figures have increased of late and we do not think that a red count of 6,000,000 is unusual in a male. These milder forms of polycythemia or erythrocytosis, which is the term applied to the secondary forms of polycythemia in contrast to the term of erythremia which is the term applied to the so-called "primary" polycythemia vera as described by Vaquez, Osler and others, do not, as a rule, present symptoms derived from the polycythemia but only symptoms derived from the underlying condition. Of course, it is true that we do not make so much distinction nowadays between primary and secondary forms of disease because it is likely that all cases of polycythemia are secondary to something. The mild forms of polycythemia, that is with red counts from 6,000,000 to 8,000,000, are not uncommon in certain forms of heart disease, of lung disease, and in any form of anoxemia. The researches on Pike's Peak, in Peru, and in the Himalayas, have shown that there is a compensatory polycythemia at high altitudes in which the red count returns to normal numbers readily when the individual comes down to low levels. In these cases, there is not the complete picture of the so-called "primary" polycythemia or erythremia. There is no considerable increase in the blood volume. It is merely the compensatory increase in the red blood corpuscles to facilitate oxygen carriage. The cyanosis of congenital heart disease, of emphysema, and of anoxemia, for example, at a high altitude is rather different from the engorged, bluish, ruddy color of erythremia. Likewise, the spleen which is fairly constantly enlarged in erythremia, is rarely felt in secondary polycythemia. Indeed, the splenomegaly may be so great as to be the presenting symptom of erythremia.

Theoretically, a number of conditions can produce a rela-

tive polycythemia and actually we can see a relative polycythemia in acute diarrhea, especially cholera, in which dehydration results sometimes in enormous increase in the number of red cells. Sweating and pulmonary edema from gas at times produces a polycythemia. High red counts and high hemoglobin estimates are frequent in cases of shock without hemorrhage. Rarely, polycythemia may be found also as a result of certain poisons including histamine and some of the snake venoms.

Somewhat over two years ago, a man presented himself with sudden blindness. The examination of his blood showed that he had around 7,000,000 red cells. In rare instances, blindness has been observed in true polycythemia. It is true that this man was treated for polycythemia and that his eyes did recover but I never believed that there was any connection between the two.

Now that our patient has gone out, we may discuss his prognosis and treatment. The prognosis is inevitably fatal but it must be remembered that this is a chronic disease, the duration of which varies from several months to many years. In the true form of polycythemia, the usual duration, even after diagnosis, which is not usually established for over a year, is a number of years. In this patient, his diagnosis was made nearly two years ago and you will recall that the onset was insidious perhaps years before this. At that time, he had a red count just under 10,000,000 and it has run along without much variation since then. As a rule, the increasing weakness and disability progress slowly with a great many minor physical and minor mental symptoms. At times, headaches and attacks of dizziness may be very severe and there may be evidence of true cerebral accidents, as thromboses or hemorrhages. For one reason or another, the autopsy material on the cerebral lesions is not great. Vascular lesions in the brain and in the extremities, especially thromboses, are common. In some of the cases, which persist for many years, the terminal blood picture is that of myelogenous leukemia. Of course, at first, this suggests that the condition might be a

tumor involving the bone marrow which affects chiefly the red blood corpuscles but which may affect the myelocytic series as well. However, these findings are probably to be related to an alteration of output of bone-marrow cells or a change in the threshold of the marrow. The bone marrow in this disease is hyperplastic and this hyperplasia extends to the parts of the bone marrow system which are ordinarily yellow. Obviously, there is no benefit in the sternal biopsy which occasionally gives us so much information in other blood diseases.

**Treatment.**—The treatment is evidently unsatisfactory. Venesection will give temporary relief to the pressure headaches and some cases are kept fairly comfortable with repeated venesection. Phenylhydrazine, usually in the form of phenylhydrazine hydrochloride, given in doses of 0.1 Gm. is often helpful. While not all cases respond to phenylhydrazine and the dosage frequently requires considerable adjustment, nevertheless, usually the red count can be brought down to normal or below. It must be remembered, however, that this (as in the case of bleeding) relieves only the symptoms of plethora. The disease progresses as does the weakness. However, treatment with phenylhydrazine has much to recommend it. It is easily carried out. Repeated bloodletting is often objected to by the patients. Irradiation therapy obviously requires the patient to travel considerable distances to secure an adequate therapy apparatus and an expert who can make the difficult calculations on which the treatment depends. At the moment, in the large medical centers, x-ray therapy to the bones is being largely employed. The exact procedure is quite complicated. The white count is used as a standard of treatment and at a certain low point, such as 3000, the treatments are discontinued.

This man has had no treatment at all because he has not seemed, until now, to present symptoms which would warrant treatment. On the other hand, the headaches increasing in severity suggest that he may be having thromboses. Certainly, the priapism he finds peculiarly distressing. It is planned to give him some rather prolonged x-ray treatments

but this is done without particular enthusiasm. Phenylhydrazine might be used or bloodletting might be equally effective.

One cannot escape from the conviction that there is a large family element in this condition. The gradations of severity of the disease in certain families is against the idea of tumor in any ordinary meaning. When the disease has established itself as a definite entity, it runs a very progressive, even if a chronic course. It would seem reasonable to suppose that a polycythemia vera, or erythremia, is secondary to some substance or condition. This substance or condition is not a recognizable form of anoxemia. The only thing in common, between the erythremia and the so-called "erythrocytosis," is the high red count.

### HEMOPHILIA\*

It is well recognized that individuals with hemophilia have a much more stormy course during early life than at any other time. This is probably due to the fact that older patients are more careful and avoid those hazards which seem to be such an integral part of the life of a young boy. It is during this early period that the more serious, and often fatal, situations arise—a truth which is well supported by the relatively small number of adults with hemophilia in comparison to the number of children with the same condition. This afternoon I would like to discuss this disturbance with you, call your attention to the various therapeutic measures which have been employed and present some of the patients whom we have treated.

This condition was first described by Otto<sup>1</sup> in 1893 and at that time attention was directed to the fact that the disease manifested itself clinically only in the male and was transmitted by the female. Following this report, various writers<sup>2, 3</sup> suggested that it not only could but did appear as a clinical disturbance in the female. However, Bullock and Fildes<sup>4</sup> in 1911 published the results of their studies on this aspect of hemophilia and concluded that the disorder occurred only in males and was transmitted by the female (Nasse law<sup>5</sup>). Further support of this "law" has been offered by Klug<sup>6</sup> who has recently restudied the Manpel family and has shown that

\* This study was supported in part by a grant from the Commonwealth Fund of New York.

through six generations the disease has been transmitted only by the female members. Davidson and McQuarrie<sup>7</sup> have reported similar statistics in eight generations of a family. However, that transmission is entirely limited to the female seems open to question as both Legg<sup>8</sup> and Mills<sup>9</sup> have presented evidence which would indicate that in rare instances the male may transmit to the female and she in turn to her children. If a man with hemophilia marries a woman who is not affected, his sons and his grandsons will not inherit hemophilia. However, should there be daughters by this marriage, they will be able to transmit the disturbance to their sons, and their granddaughters will in turn be "carriers." Theoretically it is possible for a woman to manifest hemophilia as a disease provided her father had the clinical manifestations and her mother was able to transmit it. From Macklin's<sup>10</sup> studies it would appear that the only individuals in a family afflicted with hemophilia who may marry without fear of transmitting it are the *unaffected males* and, of course, their descendants.

**Symptoms.**—Although the outstanding symptom of this disease is hemorrhage, yet it rarely manifests itself clinically before the first part of the second year of life. However, profuse and even fatal bleeding may follow such simple surgical procedures as circumcision or severing of the frenulum of the tongue during the first few days of life. The tendency to bleed not only varies with different individuals but may vary in the same individual; that is, on one occasion he may bleed very little from a moderately severe laceration while at another time a minor abrasion may prove fatal. The reason for this variation in the same individual remains unexplained although it has been pointed out that hemorrhage appears to occur more frequently during the presence of an infection than at any other time.

Trauma practically invariably precedes the appearance of hemorrhage. The injury necessary to produce bleeding, however, is very slight and not infrequently one is unable to obtain any history of trauma as the patient does not consider the usual slight blows as of significance. Since trauma does pre-

cede hemorrhage, it naturally follows that the clinical manifestations will vary according to the point of injury. Superficial or cutaneous lesions usually appear in the form of small or large hematomas and at times may prove incapacitating as well as painful. One of the most obstinate forms of superficial bleeding in epistaxis as this may persist for several days. Bleeding from loose or carious teeth is not uncommon and fatal bleeding may follow the extraction of a tooth. The viscera, with the exception of the kidneys, are rarely the site of bleeding and hemorrhage into the central nervous system is very unusual.

One of the most incapacitating forms of bleeding is hemorrhage into a joint. The development of an acute hemarthrosis is usually sudden and, as with other forms of hemorrhage, is preceded by trauma. If the hemorrhage is confined within the capsule there is no discoloration of the surrounding tissues. Associated with the local disturbance there is a mild systemic reaction characterized by an elevation of temperature, general malaise and a moderate polymorphonuclear leukocytosis. The duration of the hemarthrosis is naturally dependent upon the severity of the effusion but in the average case the swelling and pain subside within ten to fourteen days. However, with recurring attacks, chronic arthritic changes develop<sup>11</sup> and these gradually impair the function of the joint. The limitation of joint motion is not due to calcification but is the result of a fibrous ankylosis.<sup>12</sup> Atrophy of the musculature from disuse and the development of deformities are common complications among those individuals who have suffered from repeated hemarthrosis. At times these disturbances may be of such a severe nature as to preclude locomotion.

**Diagnosis.**—The diagnosis can usually be made without difficulty, as the family history, clinical course of the patient, and hematological studies immediately suggest the disease. However, during the first few days of life such conditions as hemorrhagic disease of the newborn, septicemia, congenital syphilis, and certain types of jaundice may prove confusing. Purpura haemorrhagica, a disorder which is more frequently

confused with hemophilia than any other disease may be differentiated by an examination of the blood. In hemophilia, the total number of platelets per cubic centimeter of blood is within normal limits, while in purpura (either symptomatic or idiopathic) the total number of platelets is usually reduced. Furthermore, the coagulation time and bleeding time of the blood are quite different in the two diseases.

Fig. 25.—Roentgenogram of the left knee showing arthritic changes. The joint space cartilage is almost completely eroded and there is a suggestion of slight cystic degeneration adjacent to the metaphyses of the medial condyles. There is also moderate diffuse bone atrophy. Several transverse striæ in the diaphyses proximal to the joint point to repeated periods of interference with growth during late childhood.

Although careful pathological studies of patients dying from hemophilia have been made, yet the underlying defect of the hematopoietic system has not been finally established. Time does not permit a discussion of the histopathology of this disease, but your attention is called to a recent publication by Custer and Krumbhaar<sup>13</sup> on this aspect of hemophilia.

The characteristic abnormality of the blood of these pa-

tients is the prolongation of the coagulation time of the venous blood. However, it should be noted that the coagulation time does not remain at a constant level but may vary from day to day, and may even show decided differences in the same patient within the course of twenty-four hours. Furthermore, the clotting time may even be within normal limits during a period of bleeding. There is also a variation in the coagulation time of the blood as obtained by venipuncture and that obtained by pricking the ear or the finger, a fact which necessitates the study of the coagulation time of the venous blood when any therapeutic measure is being tried as the coagulation time of the capillary blood is usually lower than that of the venous blood.

Fragility of the blood vessel walls, destruction of blood by toxins, and many other explanations have been offered as the cause of this disease. Howell,<sup>14</sup> Minot and Lee<sup>15</sup> *et al.* have suggested that although the platelets are normal in number yet they are more resistant, thereby failing to disintegrate rapidly enough to supply the necessary factor for coagulation; Klinger,<sup>16</sup> Addis,<sup>17</sup> Feissly and Fried<sup>18</sup> believe that disintegration of the platelets occurs in a normal manner. Eagle<sup>19</sup> has recently studied the various factors concerned in the mechanism of blood coagulation in individuals with hemophilia and has concluded that the platelets function normally. Mills<sup>20</sup> has offered evidence that the thrombin is not converted into prothrombin by the antithrombin. From these remarks it is apparent that there is no uniformity of opinion as to the underlying disturbance in hemophilia.

**Prognosis.**—Experience has shown that one must be careful in venturing an opinion as to the prognosis, as the slightest injury may prove fatal. Naturally, the possibility of longevity improves as the patient becomes older and is able to avoid those acts which may be accompanied by trauma. Although the coagulation time may not be markedly prolonged in all individuals with hemophilia, yet it would appear that the hazard as far as life is concerned is practically the same in all of these patients.

**Treatment.**—When one considers the numerous procedures that have been employed in the treatment of this disease, it at once becomes apparent that no one method has proved to be thoroughly satisfactory. However, before we consider any of these therapeutic measures, we might first consider what can be done to prevent its occurrence.

Since the only members of a hemophiliac family who may marry without fear of transmitting the condition are the *unaffected males* and their sons, it naturally follows that all females are potential "carriers" and therefore should not marry. In view of the fact that the only test as to whether or not the defect may be present is reproduction, the advisability of marriage and subsequent pregnancy becomes questionable. Sterilization before marriage, or the production of legal abortions should conception occur may at first glance appear rather drastic, yet when one stops to consider the seriousness of this disease and the most unfortunate clinical course of the patients, it soon assumes the cloak of respectability and saneness. However, if such measures cannot be employed, the nature of the disease should be impressed upon all those concerned.

Under *prophylaxis*, one should include the various forms of therapy that have been employed in an effort to reduce the coagulation time of the blood. Dietary régimes<sup>21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31</sup> of one nature or another have repeatedly been tried and have repeatedly been of no avail. Protein sensitization, first introduced by Vines<sup>32</sup> and subsequently elaborated upon by Mills<sup>33</sup> *et al.*, has offered a fairly satisfactory method for the control of oozing from superficial lesions; yet this procedure only affects the coagulation time of the capillary blood and does not reduce the coagulation time of the venous blood.<sup>34</sup> Even the value of this measure has been questioned by the negative results obtained by certain observers.<sup>35, 36</sup>

The observations of Birch<sup>27, 29</sup> in 1931 revived interest in the administration of ovarian substances as a possible means of reducing the coagulation time of the blood in these patients. The theory underlying this form of treatment has been based

on the generally accepted belief that the inherited trait depends on the behavior and character of chromosomes and that hemophiliacs are deficient in estrogenic substances. To date the value of this form of therapy has not been conclusively demonstrated, as various observers have reported both good<sup>39, 40, 41</sup> and poor<sup>42, 43, 44, 45</sup> results following the oral, subcutaneous, and intramuscular administration of ovarian substances. In fact, evidence has been presented which would indicate that these individuals not only possess adequate amounts of estrogenic substances but that they may even be present in excessive amounts. For many years tissue extracts, commonly known as "tissue coagulins," have been known to hasten the coagulation of blood. Schmidt,<sup>46</sup> Wooldridge,<sup>47</sup> Loeb,<sup>48</sup> Torraca,<sup>49</sup> and Mills<sup>50</sup> have repeatedly shown that such a substance could be obtained from practically every tissue in the body. The effectiveness of these coagulants has varied according to the locality from which they have been obtained. (Mills has demonstrated that an extract obtained from bovine lung has a greater potency than a similar extract obtained from other bovine organs.) Data has also been presented that would suggest that these coagulant extracts possess a certain degree of specificity for the species from which they are obtained.

In 1929, Sakurai<sup>51</sup> extracted normal human placenta and obtained a substance which when administered orally or subcutaneously reduced the coagulation time of the blood of animals. However, when it was injected *intravenously* the animals *died* as a result of intravascular coagulation. These observations, and the suggestion that tissue extracts might possess a certain degree of specificity for the species from which they were obtained, led Eley, Green, and McKhann<sup>52</sup> to investigate the possibility of obtaining a blood coagulant extract from the human placenta which might be more specific for humans than the coagulant extracts obtained from animal tissues.

The extract which has been obtained from human placentae has not only been shown to possess a strong coagulant property

but also to possess a certain degree of specificity for the species from which it has been obtained (Tabulation). Furthermore,

Bovine plasma B.....	19'45"	1'45"	3'05"
Bovine plasma C.....	12'35"	1'25"	2'36"
Bovine plasma D.....	13'29"	1'10"	2'18"

To 1 cc. of plasma was added 0.1 cc. coagulant extract (containing 1.5 mg. N per cc., and 0.3 cc. of 2.5 per cent  $\text{CaCl}_2$ ).

*in vitro* experiments have shown that the extract coagulates hemophiliac plasma just as rapidly as it does plasma obtained from normal individuals. Nineteen children suffering from hemophilia have received this extract and in 12 cases there has been a reduction in the coagulation time of the venous blood to within normal limits. Of the 7 patients that did not respond satisfactorily, 3 showed a definite reduction while 4 failed to show any response (not all of those who failed to respond received intramuscular treatment). As this reduction only persists for periods of forty-eight to seventy-eight hours, it is necessary to continue the administration of the material over an indefinite period of time. Older children and adults have proved more difficult to treat than young patients and in certain instances no response has been obtained following either the oral or intramuscular use of the coagulant. It has not been used intravenously and caution should be exercised when it is injected intramuscularly as *the intravenous route may prove fatal*.

The following cases demonstrate the results which have been obtained with this form of treatment and from these it can be seen that although the coagulant has been effective in certain instances yet in others it has proved to be of no therapeutic value.

**Case I.**—The first suggestion that this boy might be suffering from hemophilia occurred when he was two weeks of age, at which time prolonged bleeding followed the retraction of the foreskin. However, the diagnosis was not

Fig. 26.—Diagnosis, hemophilia; age of patient four years; no family history of hemophilia; coagulation time of capillary blood, eighteen minutes; of venous blood, one hour and thirty-two minutes; no response following oral or intramuscular administration.

established until he was one year old. Since the age of eight months his clinical course has been typical of that seen in so many patients suffering from this disease. Hemorrhages following minor lacerations have necessitated frequent transfusions, hematoma of the subcutaneous tissues or muscles, and the development of hemarthroses have incapacitated him for long periods of time. In an effort to modify the course of the disease he was treated by protein sensitization and although there was a reduction in the coagulation time of the capillary blood, yet there was very little change in the clinical course. Placental coagulant extract has been administered by mouth, by rectum and by intramuscular injections without any appreciable alteration in either the coagulation time of the venous blood or in the course of the disease. In fact the

patient developed rather severe hemorrhages into one ankle and one knee during the period of observation.

**Case II.**—In contrast to the first patient, this boy did not present any clinical evidence of hemophilia until five years of age, at which time he developed an acute hemarthrosis of the right knee. It is of further interest to note that when he was three years old he developed acute anterior poliomyelitis with residual paralysis of the right leg and that at that time 5 lumbar punctures were performed without any abnormal bleeding from the puncture wounds

Fig. 27.—Diagnosis, hemophilia; age of patient twelve years; no family history of hemophilia; coagulation time of capillary blood, twenty minutes; of venous blood, one and one-half hours; no response following oral administration; satisfactory response following intramuscular administration

The clinical course of this boy has been characterized by repeated hemorrhages into his knees and ankles which in the course of time have produced chronic arthritic changes within the joints. The oral administration of placental coagulant extract was followed by only a partial response as shown by a retardation in the coagulation time from seventy-five to forty-five minutes. However there was a prompt and satisfactory reduction of the venous clotting time following the intramuscular administration of 5 cc of a sterile form of the coagulant.

**Case III.**—This sixteen-year-old patient apparently presented his first symptoms of hemophilia at the time of birth for at that time he bled so profusely from the umbilicus that it became necessary to transfuse him. Since early infancy he has suffered from repeated hemarthroses, numerous attacks of severe epistaxis and frequent hemorrhages from lacerations and carious teeth. Each of the arrows as shown in Fig. 28 represent an attempt to reduce the coagulation time of the venous blood by the oral administration of the coagulant extract, and as can be seen these attempts were only partially successful.

Fig. 28.—Diagnosis, hemophilia; age of patient sixteen years; brother died from hemophilia; coagulation time of capillary blood, twenty-two minutes; of venous blood, three hours and fifteen minutes; partial but unsatisfactory response following oral administration.

Whether more satisfactory results can be obtained following the intramuscular injection of the coagulant will be determined at a later date.

Case IV.—This patient was first admitted to the hospital when he was eighteen months of age. At that time he was bleeding profusely from a minor

Fig. 29.—Diagnosis, hemophilia; age of patient, nine and one-half years; brother died from hemophilia; coagulation time of capillary blood, thirty minutes; of venous blood, two and one-half hours; satisfactory response following oral administration.

laceration of the lip and had to be transfused. His clinical course subsequent to that time has been marked by hemarthroses, repeated hemorrhages from slight wounds and frequent transfusions. Treatment by protein sensitization did appear to minimize bleeding from superficial abrasions but it failed to have any influence on the development of hemarthroses. Following the oral administration of 5 cc. of the coagulant extract there was an immediate reduction not only in the coagulation time of the capillary blood but also in the coagulation time of the venous blood. In order to maintain this reduction in the coagulation time of the blood it is necessary for this patient to take the extract every three days.

In treating *acute conditions* both local and systemic measures should be employed. If the bleeding site is accessible one may apply pressure or any of the various hemostatic substances which have been advocated such as tannic acid powder, Monsel's solution, cephalin, thromboplastin, fresh serum, etc. Hemorrhage from the kidney or from the gastro-intestinal tract are beyond such procedures. Systemic measures are usually more effective than local measures and these usually resolve themselves into one form of treatment, namely, transfusions of either whole blood or of citrated blood. In those instances in which acute conditions arise that require surgical interference one should carefully consider whether probable fatal hemorrhage is not a greater risk than the dangers of the disorder that has produced the surgical condition. Should the operation be considered as imperative, preoperative as well as postoperative transfusions should be employed.

## CLINIC OF DR. CLARK W. HEATH

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND  
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY  
HOSPITAL, THE DEPARTMENT OF MEDICINE, HARVARD  
MEDICAL SCHOOL

---

### IRON DEFICIENCY IN GIRLS: CHLOROSIS

CHLOROSIS was one of the earliest forms of anemia to be recognized as a clinical entity. It was regarded as an anemia of adolescent girls, without definite etiology, responding remarkably to iron medication. It occurred commonly during the preceding century, particularly in city dwellers under poor hygienic conditions. The disease lent itself very well to flowery literary description. Naegeli,<sup>1</sup> who gave one of the more sober descriptions, and believed that inherited characteristics played an important part in the etiology, cited from the literature the following former opinions of the causation: an inborn functional hypoplasia of the blood; a tuberculous disposition: occult blood loss from the intestine or menstrual blood loss; intestinal putrefaction; gastroptosis; hypoplasia of the vascular system; a neurosis; insufficient protein breakdown in the liver. Chlorosis is still classified today in many textbooks of medicine as an idiopathic anemia. That it has largely disappeared during the present century has been a matter for comment and wonder.

Davidson and Leitch in their monograph on "The Nutritional Anaemias"<sup>2</sup> published in 1934 made the following valuable comment upon the causative factors in chlorosis and the reasons for its relative disappearance: "Although described as a primary anaemia in all textbooks of medicine, there can be little doubt that chlorosis was essentially a nutritional

anaemia, consequent on deficient iron intake. . . . A mild degree of hypochromic anaemia is apt to occur at puberty, but when growth slows down the iron intake of the diet is usually sufficient to produce a cure. Changes in environment and habits, the achievement by working women of better hygienic conditions, including higher wages, and the dissemination of knowledge regarding the importance of diet in relation to health, have banished a serious form of *anaemia which caused an enormous degree of incapacity and economic inefficiency.*"

It is extremely desirable to take chlorosis out of the class of mysterious diseases and to place its etiology upon an understandable, scientific basis. It is true that chlorosis in severe form is uncommon today and is diagnosed as such very rarely. Nevertheless, a mild hypochromic anemia responding to iron occurring in adolescent girls is quite common, and severe hypochromic anemia is occasionally seen. In a routine examination of 38 presumably healthy student nurses between the ages of eighteen and twenty-three years, it was found that 26 per cent had a moderate anemia with the hemoglobin between 70 and 79 per cent. Out of 16 female technicians, aged twenty to twenty-six years, actively engaged in laboratory work, 4 showed a hemoglobin percentage slightly less than 80. Patek and Heath<sup>3</sup> have recently described 4 cases of severe iron-responding anemia in girls aged fifteen to sixteen years. The initial hemoglobin readings ranged from 29 to 44 per cent. The diet was remarkably poor in iron-containing foods in all 4 cases. In 1 case repeated nosebleeds and moderate menorrhagia were present and seemed partially responsible for the anemia. In 1 case nosebleeds alone seemed to be a factor. These cases corresponded closely to older descriptions of chlorosis. In addition to these instances there have been seen occasionally in the medical wards girls who have entered the hospital because of some infectious disease process such as lobar pneumonia, pleurisy with effusion or pulmonary tuberculosis who have shown on examination a marked hypochromic anemia which was alleviated by the administration of iron. The examination of the blood in all these instances showed

changes which were in all respects similar to those which occur in hypochromic anemia at other ages and in the male sex: the "nutritional" anemia of childhood, hypochromic anemia of blood loss, hypochromic anemia of pregnancy, and "idiopathic" hypochromic anemia.

In searching for the causes for iron-responding anemia in girls who presented no history of any great blood loss, attention was directed to the iron needs of the body and to the metabolism of iron. It was apparent from the literature that, although evidence is fragmentary and unsatisfactory, a diet restricted in iron, providing starvation does not exist, cannot result in any appreciable loss of iron from the body. In other words, a negative iron balance cannot be achieved in man by altering the diet alone when adequate calories are given. For example, Lintzel<sup>4</sup> found man in iron balance when the diet contained as little as 1 mg. of iron daily. The normal excretion of iron in the urine is practically negligible. In animal experimentation iron-responding anemia has apparently never been achieved by giving diets poor in iron, unless animals are young and growing, unless pregnancy takes place, or unless the animals are bled. It is evident, therefore, that diet poor in iron cannot be responsible alone for iron deficiency. Iron loss of some sort other than metabolic loss of iron in the urine and stools must occur. That blood loss represents a large source of iron loss is obvious since the blood is very rich in iron, containing about five times the proportion of iron of any other organ of the body under ordinary circumstances. Menstrual loss of blood, although small (averaging 50 cc. of blood each menstrual period), is constant and over many months' time represents a considerable loss, amounting on the average to nearly 1 mg. of iron a day. In pregnancy the fetus demands a certain portion of the mother's iron to supply its own body iron and iron stores. In lactation there is a certain small loss of iron equaling roughly in daily averages the amount of iron lost in normal menstruation. In growing infants and children there is a large demand for iron to supply the increasing mass of hemoglobin in the expanding blood volume.

During the first year of life the circulating hemoglobin (which embraces about four fifths of the total functioning iron of the body) approximately doubles. In effect, the growing infant "bleeds" into his own increasing blood volume. These factors, growth, pregnancy, lactation and blood loss, produce a demand for iron which must be considered first in the etiology of iron deficiency. If this demand is not met by an adequate supply of iron from the food or from medication, iron stores may become exhausted and anemia may result.

In Fig. 30 is shown the average normal annual iron requirements for males and females from birth to twenty-six years

Fig. 30.—Annual physiological iron requirements for males and females, derived from figures for growth, menstruation and pregnancy.

years. Requirements for males are derived from growth statistics, for females from growth statistics together with probable losses of iron from menstruation and pregnancy. It is interesting that iron-responding anemia is seen clinically most commonly at the very times and in the same conditions that the iron demands are greatest: in infancy and early childhood after puberty, in pregnancy and in females much more commonly than in males. These iron demands must be met by adequate iron in the food, which must be absorbed through a healthy intestinal membrane, or an iron deficiency may result.

At about the time of puberty there is an acceleration of growth. This, together with the demands for menstrual loss of blood in girls, produces an annual iron requirement which is proportional to the requirement for a normal pregnancy. It is therefore quite apparent that an iron deficiency can result in girls after puberty if one of a number of factors are upset. The normal factors are: normal growth and menstruation, a healthy appetite, a good diet and a healthy gastro-intestinal tract. Abnormal factors which may condition an iron deficiency are: abnormally rapid growth, excessive menstruation or bleeding elsewhere, a diet poor in iron or poor appetite and such gastro-intestinal disorders as achlorhydria and prolonged diarrhea. The following 2 cases of iron deficiency in girls illustrate how the analysis of responsible factors can explain "chlorosis" as it is seen today, and how blood loss can easily qualify the hemoglobin level in girls after puberty.

Case I.—M. M., aged fourteen years, a white American schoolgirl, of Irish descent, was admitted to the hospital complaining of vomiting of blood. Four days before admission she went on an outing when she indiscriminately stuffed herself with a variety of food. Two days before admission she felt ill, dizzy and nauseated on rising in the morning. In the afternoon she suddenly vomited bright red blood in considerable amount, the exact amount unknown. She was put to bed and the family physician advised hospitalization.

The patient considered herself always fairly healthy. She could run, play and swim as well as other girls. However, three to five years previously she was considered underweight at school. For about four years she had mild epigastric distress and eructation of gas after each meal. One year previously, after a brief, colicky epigastric pain she visited her doctor who diagnosed her "anemic" and prescribed some iron pills. She felt improved after taking these pills. She discontinued taking them after about three months.

Two months before admission the patient had epistaxis lasting fifteen minutes, soiling five handkerchiefs. There was no other history of bleeding. She did not consistently inspect her stools but noticed no blood or tarry stools.

Menstruation began two years before admission. Periods occurred monthly with the exception of a lapse of four months, eight to four months previously. Flow persisted for five or six days. For four days 5 pads daily were saturated. Occasionally menstrual blood was clotted. Periods were accompanied by moderate pains for two days.

The patient's diet contained 1 or 2 eggs daily but somewhat reduced amounts of meat and vegetables. There was an increased ingestion of carbohydrates in the form of bread, cookies and cake. Apparently she had a good appetite, but the amount of food which she stated she consumed was perhaps

exaggerated because the cost of the diet was high and the family was poor. The approximate daily iron content of the diet was 14 mg.

*Family History.*—The father was living and well. The mother was examined briefly. She was forty-four years of age, considered herself well. She had a tendency to chronic, sore fissures at the corners of the mouth. There was slight atrophy of the tongue papillae. There was no koilonychia. She was a chronic tea drinker, consuming 7 or 8 cups a day, and a slice of bread and butter with each cup. She ate very sparingly of meat and vegetables. Her red blood cells were 5,250,000 per cubic millimeter, her hemoglobin 94 per cent. The patient's sister, aged thirteen years, was considered well but on examination showed a moderate anemia and is discussed as Case II.

*Past History.*—The patient was born and had always lived in Massachusetts. She had measles in childhood but no other diseases. A review of the cardiorespiratory, gastro-intestinal, genito-urinary and neuromuscular histories revealed nothing remarkable.

*Physical Examination.*—The patient was a pale, freckle-faced girl in no distress. The eyes, ears and nose were not remarkable. The tongue was moderately coated and not atrophic. There was no lymph node enlargement. The lungs were normal. The heart was not enlarged, the rate was regular, rapid and the sounds of good quality. There was a soft systolic murmur heard best at the apex. The blood pressure was 85 systolic, 75 diastolic. There was no tenderness of the abdomen. The liver, spleen and kidneys were not palpable. The knee and ankle jerks were equal and active. There was no pitting edema of the extremities.

*Laboratory Findings.*—The red blood cells were 2,900,000 per cubic millimeter. The hemoglobin was 54 per cent; the hematocrit was 26.7 per cent; mean corpuscular volume: 92 cu.  $\mu$ ; mean corpuscular hemoglobin concentration 31 per cent; mean corpuscular hemoglobin: 29 micromicrograms. Nine days later the red blood cells were 3,640,000 per cubic millimeter; hemoglobin 56 per cent; mean corpuscular volume 77 cu.  $\mu$ ; mean corpuscular hemoglobin 24 micromicrograms. The reticulocytes were 5.8 per cent. The icteric index was 3. The Hinton test was negative. In the blood smear the red cells showed increased variation in size and shape, moderate basophilia and many cells were small and achromic. The blood platelets were increased. The white blood cells numbered 6800 per cubic millimeter. The differential count showed polymorphonuclear neutrophils, 66 per cent; stab forms, 15 per cent; eosinophils, 1 per cent; basophils, 0.5 per cent; lymphocytes 27 per cent; monocytes, 4 per cent. The stools were guaiac positive during the first few days of entry, but subsequently were negative. Gastric analysis performed three weeks after entry showed normal acidity of the gastric contents.

Roentgen examination of the stomach with barium on two occasions revealed the presence of a small ulcer high in the lesser curvature.

*Course in the Hospital.*—The patient was given a Sippy diet with gradually increasing variety of food. After thirteen days of observation the hemoglobin remained at 54 per cent, and the reticulocytes diminished to about 1 per cent. Iron and ammonium citrate, 1 Gm. daily, was then administered. The reticulocytes increased to a peak of 6.5 per cent on the sixth day. The hemoglobin increased rapidly to 80 per cent after twenty-one days, an average

gain of about 1.2 per cent per day. No further digestive symptoms occurred. The patient was discharged with instructions to take ferrous sulphate, 12 grains daily. The hemoglobin, red blood cells and Wintrobe characteristics remained normal on subsequent visits to the hospital.

**Case II.**—A. M., aged thirteen years, schoolgirl. This girl was the younger sister of M. M., Case I. She was observed to be quite pale but claimed never to be tired or to have any symptoms of ill health. Her periods commenced six months previously. These occurred monthly, lasted four to five days, required 3 to 4 pads daily; sometimes large pads. She thought that she flowed somewhat more than her sister. Her diet was similar to that of her sister with the exception that she liked meat and ate it daily. She partook of rather excessive amounts of bread and other carbohydrate. About three years previously she had quite frequent, moderate attacks of epistaxis. For the past eight months she had epistaxis three times, requiring 2 or 3 cloths and lasting fifteen to twenty minutes. Three years previously in an accident she was said to have bled considerably from a cut on the forehead. Physical examination revealed no definite abnormalities in this girl except moderate pallor.

**Laboratory Findings.**—The red blood cells numbered 4,850,000 per cubic millimeter. The hemoglobin was 79 per cent. There were striking changes of the red cells in the blood smear; there was definitely increased variation in size, some in shape, and most of the cells were rather pale. The blood platelets and white blood cells appeared normal.

The patient was instructed to take ferrous sulphate, 4 grains twice daily. At the end of five weeks the red blood cells numbered 4,895,000 per cubic millimeter and the hemoglobin was 88 per cent. The characteristics of the red blood cells in the smear had improved greatly.

These two girls on examination both showed the characteristics of a hypochromic anemia or iron deficiency anemia, and both responded to iron medication with alleviation of the anemia. The anemia in the second patient was slight. It was more apparent on examination of the blood smear that there was abnormality of blood formation. Because the girls were sisters, nearly of age, grew at a similar rate and partook of similar diets, it is probably justifiable to assume that the blood condition of the second girl was similar to that of the first before gastric bleeding occurred. In other words, Case II serves as a control to Case I.

Annual height and weight measurements of the two girls were obtainable through the schools. The probable blood volumes per meter of body surface were estimated and from these figures the annual iron requirements for growth were

exaggerated because the cost of the diet was high and the family was poor. The approximate daily iron content of the diet was 14 mg.

*Family History.*—The father was living and well. The mother was examined briefly. She was forty-four years of age, considered herself well. She had a tendency to chronic, sore fissures at the corners of the mouth. There was slight atrophy of the tongue papillae. There was no koilonychia. Hematemesis.....	0.50		
Total.....	2.03	1.02	0.89

\* Onset of menses (average normal age of onset is fourteen years).

given. These are estimated conservatively from the following figures: 50 cc. of blood for each menstrual period, 10 cc. of blood for each bout of epistaxis, 1160 cc. of blood for the gastric bleeding in Case I, 50 cc. of blood for the loss which occurred from the wound in Case II.

Although the iron requirements for growth in the two patients were similar to the average normal, the total iron requirements were greatly in excess because of the early onset of menses and because of pathological blood loss. In Case I the total iron requirement for growth and blood loss between the ages of twelve and fourteen years was 1.42 Gm. If spread out evenly over the course of the two years this would represent an average daily requirement of about 2 mg. of iron. Experience shows that this is a relatively large daily iron requirement. Although the daily iron of the diet of the patient was about 14 mg., only a small portion of this is available for absorption. More knowledge is necessary concerning the amount of iron retained from the food in human patients with

anemia before it can be said that a daily iron requirement of more than 1 mg. can always be met by the iron of the diet. Iron losses due to growth or bleeding exceeding 1 mg. a day are apt to result in hypochromic anemia, and this fact would lead to the belief that this is the usual limit of availability of iron from the food of the ordinary diet. Although a requirement of 2 Gm. of iron for six years, which was present in Case I, seems very small, it is large compared with the total amount of iron of the body at this age, which is about 3 to 4 Gm. Losses of nitrogen, calcium or other necessary substances involving over the course of years one half the total of the body surely might lead to deficiency syndromes unless adequately met by a suitable supply.

It is quite likely that the two patients under consideration received from their mother an inadequate store of iron at birth. We have no evidence that the mother was deficient in iron, but we do know that she subsisted on a poor diet and that she had slight atrophy of the papillae of the tongue and a tendency to sore fissures at the corners of her mouth, signs which are characteristic in "idiopathic" hypochromic anemia occurring in women of this age. It can be supposed that the daughters never built up adequate iron stores in early school years and that they entered puberty, if not anemic, at any rate without available iron stores.

The frank blood loss by hematemesis in Case I apparently takes it out of the classification of typical chlorosis. Nevertheless, hematemesis has been mentioned in the older literature as not unusual in chlorosis.<sup>5</sup> The characteristics of the anemia, the obvious iron deficiency and the improvement of the blood after iron medication are in no way different in cases of hypochromic anemia in girls having no obviously increased blood loss. Modern methods of examination enable us to locate the source of bleeding, in this case a gastric ulcer.

Since the etiology of chlorosis depends upon conditions which are universally current, such as growth, blood loss and inadequate diet, it is unlikely that the disease should completely disappear. Indeed, chlorosis has not disappeared.

It is quite likely that the two patients under consideration received from their mother an inadequate store of iron at birth. We have no evidence that the mother was deficient in iron, but we do know that she subsisted on a poor diet and that she had slight atrophy of the papillae of the tongue and a tendency to sore fissures at the corners of her mouth, signs which are characteristic in "idiopathic" hypochromic anemia occurring in women of this age. It can be supposed that the daughters never built up adequate iron stores in early school years and that they entered puberty, if not anemic, at any rate without available iron stores.

The frank blood loss by hematemesis in Case I apparently takes it out of the classification of typical chlorosis. Nevertheless, hematemesis has been mentioned in the older literature as not unusual in chlorosis.<sup>5</sup> The characteristics of the anemia, the obvious iron deficiency and the improvement of the blood after iron medication are in no way different in cases of hypochromic anemia in girls having no obviously increased blood loss. Modern methods of examination enable us to locate the source of bleeding, in this case a gastric ulcer.

Since the etiology of chlorosis depends upon conditions which are universally current, such as growth, blood loss and inadequate diet, it is unlikely that the disease should completely disappear. Indeed, chlorosis has not disappeared.

That it is much less common seems not difficult to explain. In the present century girls and women in general have become emancipated to a large extent from an indoor existence. The principles of hygienic life and diet have been widely advertised and adopted. Outdoor activities are no longer taboo among young women as the general life of the two sexes has become more and more comparable. A healthy appetite usually is an effect of freedom of life and exercise and means in general a good diet.

A thorough knowledge of the causative factors of chlorosis can be helpful to the clinician in a number of ways. The presence of an iron deficiency should always be considered as a serious symptom, for although the anemia itself rarely is serious, it may indicate the presence of serious pathology. The point of view of regarding a "secondary anemia" as merely a very minor abnormality can lead an observer into very grave error. For example, "secondary anemia" may be the result of a neoplasm of the stomach which is silently bleeding. When confronted with a case of anemia in a girl and especially in a boy, the clinician should make sure, before diagnosing "secondary anemia" or chlorosis that the causes for an iron deficiency are present. "Idiopathic" cases of iron deficiency apparently do not exist. If the anemic girl gives a perfectly normal history of growth, menstruation, diet, and absence of blood loss it is extremely unlikely that one is dealing with a case of chlorosis. Other causes for anemia must be searched for, some examples being: infectious disease, such as pulmonary tuberculosis; chronic nephritis; occult bleeding from some gastrointestinal pathology; hemolytic anemia; myxedema.

The treatment of iron deficiency in girls is in no way different from the treatment of iron deficiency at other ages. Large doses of inorganic iron preparations are indicated, common preparations in use being: ferrous sulphate (daily average dose: 12 grains); iron and ammonium citrate (6 Gm. daily); reduced iron (2 to 4 Gm. daily). It is advisable to commence with small doses and gradually increase them. Medication should continue for many months after the anemia is alleviated

in order to build reserve stores of iron. It is perfectly appropriate to give small daily prophylactic doses of iron to girls at puberty, for example, 1 pill a day containing ferrous sulphate, 3 grains, or 1 level teaspoonful of iron and ammonium citrate scales dissolved in milk, daily.

## CLINIC OF DR. LOUIS K. DIAMOND

FROM THE DEPARTMENT OF PEDIATRICS, HARVARD MEDICAL  
SCHOOL AND THE INFANTS' AND CHILDREN'S HOSPITALS

---

### CONGENITAL HEMOLYTIC ANEMIA IN INFANCY AND CHILDHOOD

CONGENITAL hemolytic anemia has been recognized since its descriptions by Minkowsky<sup>1</sup> in 1900 and by Chauffard<sup>2</sup> in 1907. In an excellent review of this disease entity in 1922, Tileston<sup>3</sup> detailed the characteristics of the disturbance, the differential diagnosis, the complications and the treatment. Since then, numerous case reports and reviews have stressed the diagnostic features, especially as they occur in adults. In infancy and in childhood, however, the disease may manifest variations from the usual course. These consist chiefly of more profound anemia, cardiac enlargement and sometimes decompensation, and interference with proper skeletal growth. It is the purpose of this presentation of 6 illustrative cases chosen from a group of 20 studied here, to call particular attention to these variations in the disease as it occurs in the younger age group.

The chief characteristics by which the diagnosis is established appear equally well in congenital hemolytic anemia in infancy and in childhood. These are, a chronic or recurring type of anemia associated with relatively mild icterus becoming accentuated during crises of hemolysis; enlargement of the spleen; increase in amounts of urobilin in the urine and stools; increased fragility of the erythrocytes in hypotonic saline solutions; elevation in percentage of reticulocytes in the circulation out of proportion to the degree of anemia

present; and a tendency for the erythrocytes to be microcytic and globular.

As is true of many other diseases seen both in adult life and in infancy and childhood, these characteristics of the disease may be more marked in the young. For example, jaundice may not be as prominent a symptom, whereas the anemia may become so severe especially during crises of hemolysis that death may result from lowering of erythrocyte and hemoglobin levels and subsequent anoxemia. The well-known saying that "adults with the disease are more jaundiced than sick" should be reversed to read "children, and especially infants, with this condition are more sick than jaundiced." The spleen may become so enlarged as to fill the whole left side of the abdomen; the blood changes are generally more severe, that is, the anemia is more profound, the cells show much more tendency to variation in shape, the reticulocytes may rise to tremendous percentages, such as in one case reported from this clinic in which they numbered about 90 per cent of all the erythrocytes; and the fragility test may show hemolysis beginning in normal isotonic saline solutions. The other outstanding changes to be met with in congenital hemolytic anemia in the young will be illustrated in the cases detailed below.

**Case I.**—A four-and-one-half-month-old female infant was brought to the hospital on account of anemia of about two months' duration.

The family history showed no other instances of anemia or jaundice in any individuals related to the patient. Three other siblings were living and well. Their blood examinations as well as those of the parents offered no suggestion of a condition similar to the patient's.

The past history had been unimportant until the time of onset of the present illness. The infant had been born by normal delivery, at term; the birth weight was 8 pounds 3 ounces. She had been placed under the care of a competent physician immediately after birth and had grown and gained well. There had been no jaundice or pallor.

The present illness began at the age of two and one-half months when the parents noticed a definite pallor which gradually increased in severity during the next two weeks. At the age of four months this pallor was very marked; a determination of the blood levels at this time showed an erythrocyte count of 2,000,000 per cubic millimeter and a hemoglobin of 40 per cent. In the stained smears of the blood there appeared to be many nucleated erythrocytes. At the suggestion of the family physician, liver was given but produced

no beneficial effect. There was an increase in pallor during the two weeks before entry and slight icterus began to be visible. There was also occasional transitory feverishness. No drugs had been administered.

Physical examination revealed a well developed and nourished infant weighing 12 pounds. She was bright and alert. There was marked pallor of the skin and mucous membranes and slight icterus of the skin and sclerae. The heart was enlarged to percussion and a loud, blowing, systolic murmur could be heard over the entire precordium. The abdomen was full and distended. The spleen filled the left flank to the level of the crest of the ilium and extended to the midline as far as the umbilicus. The liver was enlarged about 4 cm. below the costal margin.

Laboratory data included: erythrocytes 1,500,000 per cubic millimeter; hemoglobin 24 per cent; uncorrected white blood count 45,000 per cubic millimeter; in the stained smears there were 40 nucleated erythrocytes per 100 nucleated cells, as well as 31 per cent reticulocytes. Many of the leukocytes were immature. The fragility of the erythrocytes in hypotonic saline solutions showed hemolysis beginning at 0.85 per cent and complete at 0.38 per cent (control 0.46 to 0.22 per cent). The van den Bergh test was indirect and showed four times normal bilirubin content. In the urine and the stools there were excessive amounts of urobilinogen. Blood cultures and stool cultures yielded no growth of pathogenic organisms. The Wassermann and tuberculin tests were negative. Roentgenograms showed a moderate enlargement of the heart but no other abnormalities. The bones seemed normal.

Course: during the first week of observation, the temperature was only occasionally elevated above 100° F. There was no evidence of acute or chronic infection or toxemia. The blood levels failed to rise in spite of the high reticulocytosis and evidences of continued increased blood destruction were present. Transfusion with matched citrated whole blood was given on two successive days and then operation performed. A very large, firm, rough-surfaced spleen, weighing 144 Gm., was removed. Further observation at the time of operation showed an enlarged but normal appearing liver and a moderate enlargement of the mesenteric lymph nodes. Following operation the convalescence was normal and a rapid improvement in blood levels occurred. Five days post-operatively, the erythrocytes numbered 2,300,000 per cubic millimeter and the hemoglobin was 36 per cent; eight days later the red blood cells numbered 4,000,000 and the hemoglobin was 59 per cent. The icterus of the skin and sclerae and bilirubinemia rapidly subsided. The infant was discharged twelve days after operation, in excellent condition. During the ensuing three years the blood levels have remained within normal limits, the patient has gained and grown in normal fashion and has had no further attacks of jaundice or pallor. The excessive fragility of the erythrocytes has slowly decreased although at the last examination the values were still somewhat above normal. Roentgenograms have shown relative decrease in the size of the heart in comparison with the chest and the cardiac murmur has disappeared.

*Comment.*—Although there was no history of the condition occurring in this patient's family, the first symptoms of

the disease were seen at the very early age of two and one-half months. The rapidity of development of the anemia was characteristic of the progress of the disease in the young infant during a hemolytic crisis.

The physical examination showed much greater pallor than jaundice; there was enlargement of the heart with loud, blowing murmurs resulting from the severe anemia; and there was great enlargement of the spleen, as well as of the liver. Nucleated erythrocytes in addition to reticulocytes were present in the circulating blood in large numbers. Because of the relatively acute course and age of the patient there had been no time for development of skeletal changes discernible by roentgenogram. Operation produced a very rapid and satisfactory improvement in the levels of erythrocytes and hemoglobin, as well as complete relief of the symptoms for which the patient had been admitted. Frequent observations during the following three years have revealed no tendency for recurrence of hemolytic crises and growth and development were normal. In summary, this represents a most satisfactory result from early diagnosis and treatment in a young infant with the disease.

**Case II.**—A six-month-old male infant was referred here by his family physician because of pallor, and an abdominal mass.

The family history was unessential. No other child had had a similar complaint. No relative had been known to have pallor or jaundice.

The past history related that the child had been born at term, weighing 8½ pounds. There had been no appreciable jaundice or pallor in the first months of life. Breast feeding had been well taken and the gain in weight had been very satisfactory.

When the infant was four and one-half months of age, the parents noticed definite pallor of his skin and mucous membranes. This had gradually increased for the following three weeks. When seen by the family physician at five and one-quarter months, there was a moderate degree of pallor and slight icterus of the skin and sclerae. In the ensuing three weeks until hospitalization occurred, the pallor became very marked, there was occasional feverishness, severe anorexia and a slow swelling of the abdomen. The icterus had faded somewhat. The stools had been noted to be a dark orange-brown in color and the urine was likewise orange colored. One day before entry, the infant's color became very "poor"; he was lethargic and refused to nurse at the breast.

Physical examination revealed a well-developed and well-nourished infant. The skin and mucous membranes were extremely pale and only slight icterus.

was visible in the sclerae. The respirations were rapid and deep. The heart was enlarged 2 cm. outside the nipple line to the left. There was a gallop rhythm, the rate was 180, and loud systolic and diastolic murmurs were heard all over the precordium. The abdomen was protuberant with a large firm splenic mass reaching to the crest of the ilium on the left and an enlarged liver extending down to the level of the umbilicus on the right.

Laboratory examinations included: a red blood count of about 1,000,000 per cubic millimeter; reticulocytes numbering about 80 per cent; many nucleated red blood cells in the stained smear; the majority of the normal erythrocytes were small globular cells, well-filled with hemoglobin. The urine was orange-colored and contained urobilin in concentrations of about one hundred times normal. A fragility test partially performed by the use of capillary blood showed hemolysis in saline solutions beginning at 0.8 per cent.

Shortly after entry, and before transfusion could be performed, the patient's respirations ceased.

*Comment.*—This infant began about the fourth month of life to develop progressive pallor and weakness. When first seen in the hospital, congenital hemolytic anemia was suggested by the course, the symptoms and characteristic blood changes. However, the anemia had progressed to so serious a degree and signs of cardiac decompensation due to anoxemia and anemia were so marked that the first efforts needed to be directed toward prolonging the life of the child by transfusion. Unfortunately, before this could be done, death occurred. This may serve to illustrate, therefore, the much smaller margin of safety which occurs in the course of hemolytic crises of congenital hemolytic anemia in infancy. Whereas it is not uncommon to wait for a recurrence of these crises in the adult before confirming the diagnosis and suggesting surgical treatment, in the infant it is advisable to perform the life-saving operation of splenectomy as soon as the diagnosis can be confirmed, even during, or immediately after, the first hemolytic crisis.

**Case III.**—A five-year-old boy was referred to the hospital by his family physician because of frequent attacks of jaundice.

The history was somewhat inaccurate because of language difficulty and lack of observation by the parents. The father had always been well but the mother was said to have been pale and frequently somewhat jaundiced from early in childhood until she had reached adult life. Since her marriage she had been moderately well and free of jaundice or definite pallor. There had been no other pregnancies.

The past history related that the child had been healthy throughout the first year of life. After that time, he had exhibited moderate pallor of the skin and mucous membranes and occasionally "looked yellow." However, he had not been taken to a physician nor been treated for this disturbance because of the mother's personal experience. The appetite had been poor especially when he was "yellow looking." At such times he frequently complained of severe abdominal pain, relieved by vomiting.

At three years of age, following an attack of measles, the patient became much more pale and jaundiced and complained of severe abdominal pain radiating from the umbilicus to the left side and accompanied by vomiting. This illness subsided after one week but left him very pale, weak and tired. From this time on, there had occurred frequent attacks of abdominal pain radiating to either side, increasing in severity, and always accompanied by feverishness, jaundice and pallor.

Seven months before entry (at the age of four and one-half years) during a recurrence of the acute attack of abdominal pain, a physician made the diagnosis of ruptured appendix with peritonitis because of the tenderness and spasm of the abdomen. A laparotomy was performed. At operation, a long, slightly reddened, and adherent appendix was removed, and it was noted that both the spleen and the liver were much enlarged and the mesenteric lymph nodes seemed much larger than usual. While in the local hospital for this surgical procedure, the patient was noted to be moderately jaundiced and the red blood count found to be 3,000,000 per cubic millimeter with hemoglobin slightly below 60 per cent. The urine was said to be normal excepting for its dark amber color.

Following operation the patient seemed slightly improved, the icterus gradually faded during the course of one month and his color became more ruddy. However, five months before entry, there was another attack of severe generalized abdominal pain lasting one week, during which his jaundice returned, his pallor increased, and the urine and stools were once more dark. Similar episodes occurred about once a month up to the time of entry.

Physical examination revealed a pale small boy with brownish yellow color to his skin and pallor of his lips and mucous membranes. There was enlargement of the heart and loud murmurs were heard all over the precordium. The liver and the spleen were enlarged to the level of the umbilicus. Laboratory examinations showed an erythrocyte level of 3,700,000 per cubic millimeter, hemoglobin 58 per cent; reticulocytes 10 per cent; white blood cells 15,000 per cubic millimeter with occasional immature cells and 2 nucleated erythrocytes per 100 leukocytes. The fragility of the erythrocytes in hypotonic saline solutions showed hemolysis beginning at 0.76 per cent and complete at 0.33 per cent. Urobilin excretion in the urine and stools was markedly increased. Roentgenograms revealed marked retardation in growth and development of the skeletal system as well as enlargement of the heart, the liver and the spleen.

During the brief stay in the hospital, the patient remained afebrile and relatively well. Operation was urged but permission was absolutely refused by the parents. Following two visits to the dispensary during which the patient's physical and laboratory findings remained essentially unchanged, the child was not seen again. Subsequent history disclosed that recurrences of

abdominal pain, jaundice and pallor continued at increasingly frequent intervals and that about one year after his last hospital visit, during one of these attacks, the child quickly failed and died.

*Comment.*—A review of this case impresses us with the frequent occurrence of severe abdominal pain accompanied often by vomiting and some fever during the hemolytic crises of the disease in childhood. Frequently the pain is associated with tenderness and rigidity of the abdomen and therefore simulates the presence of an acute surgical abdomen. The differential diagnosis of congenital hemolytic anemia from an acute surgical condition may be difficult, especially if jaundice is not too prominent and if the character of the red blood cell changes is not appreciated. In this boy's case the diagnosis of ruptured appendix with peritonitis was made and only during the operation, when the enlargement of the liver and spleen were noted, was it appreciated that some other condition might have accounted for the abdominal symptoms. Although the diagnosis of congenital hemolytic anemia was later substantiated, the previous unhappy experience with an unsuccessful operation influenced the parents against permitting another operation. The subsequent course of the patient was typical of the disease in that the attacks became more severe and more frequent and during one of these the child succumbed, presumably from the usual sequence of events: anemia, anoxemia, cardiac enlargement and decompensation. One other point of interest in this case is the presence of marked retardation in growth and development of the skeletal system which is so frequently seen in the growing child afflicted with a chronic, recurrent disease.

*Case IV.*—A two-and-eight-twelfths-year-old girl came to the hospital because of persistent pallor.

The family history was essentially negative in that neither the father, the mother nor other children, nor any relatives were suffering from a similar complaint.

The past history showed that the infant had been fairly well for the first six months of life and then had begun to "look pale." The appetite had become poor. Measles, pertussis and subsequent bronchitis before the second year had increased her usual pallor.

Following the recurrence of severe bronchitis at the age of two years, the whiteness of her skin and mucous membranes became much more marked and there was a slight degree of jaundice visible in her sclerae. This persisted until the time of her entry.

Physical examination revealed a small, poorly developed and nourished female child, whose skin was lemon yellow and whose lips and mucous membranes were blanched. She appeared somewhat drowsy and apathetic. The respirations were rapid as was the pulse. The heart was enlarged 3 cm. to the left of the nipple line; a systolic murmur could be heard all over the precordium. The spleen was moderately enlarged, about 4 fingerbreadths below the costal margin, and the liver likewise was enlarged and tender to palpation. Shifting dullness and a fluid wave were demonstrable in the abdomen.

Laboratory examinations: the erythrocyte count was 1,700,000 per cubic millimeter; the hemoglobin level 30 per cent; leukocytes numbered 9000 per cubic millimeter. Stained smears of the blood revealed small cells well-filled with hemoglobin and moderate poikilocytosis. The reticulocytes numbered 15 per cent and there were 8 nucleated erythrocytes per 100 leukocytes. Fragility of the erythrocytes in hypotonic saline solutions showed hemolysis beginning at 0.68 per cent and complete at 0.46 per cent; at a second examination, hemolysis began at 0.76 per cent and was complete at 0.46 per cent. The urine and stools showed increased amounts of urobilinogen. Roentgenograms confirmed the marked enlargement of the heart, retardation in growth and in development of the carpal centers, marked thinning of the cortices of the bones of the extremities with increased width of the medullary portions.

The patient was transfused and then sent to the Convalescent Home for the purpose of improving her nutritional state. During the two months of care there, she gained rapidly in weight and in strength. As soon as she returned home, however, another hemolytic crisis occurred, necessitating readmission to the hospital.

Following transfusion, splenectomy was performed (at the age of three years) with the removal of a large, firm spleen. There occurred an uneventful convalescence, and the patient was discharged home three weeks following operation, showing marked improvement in her general condition as well as her blood, though a slight degree of anemia still persisted.

During the ensuing nine years this child has been seen at regular intervals. She has remained constantly free of any evidence of increased hemolysis of the red blood cells, has grown and gained very well. At a recent examination, the only discernible abnormalities were a slight persistence of the tendency to increased fragility of the erythrocytes in hypotonic saline solutions (0.54 to 0.3 per cent) and slight retardation in ossification of the carpal centers (about one year below the chronological age, whereas at the time of operation they were two and one-half years below the chronological age).

*Comment.*—In this patient's illness the following details stand out particularly clearly. Besides the usual findings characteristic of the disease there was present much more than the usual evidence of interference with bodily function due to re-

current anemia. These were marked cardiac enlargement with cardiac decompensation, as evidenced by the very rapid pulse and respiration and tenderness of the liver on palpation, as well as shifting dullness in the flanks. In addition, roentgenograms showed retardation in growth and development of the carpal centers corresponding to an estimated age of one year instead of the chronological age of three years. Likewise, there was marked thinning of the cortices of the bones of the extremities with increase of the medullary portions, a picture which we have learned to recognize as characteristic of hypertrophy of the medullary substance due to chronic anemia of the congenital types<sup>4</sup> (*i. e.*, congenital hemolytic anemia, sickle-cell anemia and Mediterranean anemia of the Cooley type).

Following operation the patient made a splendid recovery and in the ensuing nine years there has been no further hemolytic crisis, although the tendency to increased fragility of the erythrocytes in hypotonic saline solutions remains. In addition the retardation in the growth and development has tended to improve, although it has not been entirely cured in this period of time. However, the bones no longer show evidence of increased medullary substances due to hyperactive, hyperplastic marrow tissue. So that in this case the operation not only controlled the tendency toward hemolytic crises but also radically changed the patient's growth and development and restored her to normal health.

Case V.—A girl, of eleven and nine-twelfths years, was brought in because of recurrent attacks of jaundice since three years of age.

Family history revealed that the father had had a mild recurrent type of jaundice since early youth but had never suffered any discomfort from this nor exhibited pallor or symptoms of anemia. Since his marriage thirteen years before, these attacks had been less frequent and his health had remained good. The two other children had no symptoms similar to the patient's.

Past history at three years of age the child had had a moderately severe attack of fever, jaundice and increasing pallor. This had lasted one week and then subsided leaving her pale and weak looking. The attacks had increased in frequency and severity from the time of onset, at first occurring about twice a year and more recently about six to eight times per year. As a consequence, she had been restricted in her activity and had been unable to attend school. The attacks started characteristically with a nonradiating, dull epigastric pain about 6 in the left upper quadrant, not colicky in type. This persisted for sev-

eral hours, to be followed by fever, then jaundice and finally pallor. Anorexia from the onset and occasional vomiting were noted. During the attacks, the stools and the urine both became dark yellow to orange in color. This color persisted for a few days and then faded. The skin discoloration usually remained for a week or two and then improved slowly.

Physical examination at entry revealed a girl, small for her age but fairly well nourished. There was a slight icterus of the skin and sclerae and pallor of the lips and mucous membranes. The heart was somewhat enlarged to the left with a loud systolic murmur best heard at the base. The spleen was palpable 4 fingerbreadths below the costal margin and the liver 3 fingerbreadths below the costal margin.

Laboratory examinations showed the erythrocyte count to be 3,200,000 per cubic millimeter; hemoglobin 10 Gm. (59 per cent); leukocytes 6800 per cubic millimeter; platelets 224,000 per cubic millimeter. Stained smears of the blood showed 7 per cent reticulocytes, small globular erythrocytes and moderate poikilocytosis. The icterus index was 40 and the van den Bergh test indirect. The fragility of the erythrocytes in hypotonic saline solutions showed hemolysis beginning at 0.85 per cent and complete at 0.38 per cent. Quantitative determinations of urobilin excretion in the urine and stools showed 3100 mg. in twenty-four hours as compared to a normal average of 80 mg. for this age.

Roentgenograms of the hands revealed a carpal development corresponding to nine years (instead of about twelve years) and general delay in bone growth. Likewise the medullary cavities of the long bones seemed increased in width.

Splenectomy was performed with relatively little difficulty. On the sixth day following this operation the platelets which had been rising slowly as is usual following this operation reached a level of 900,000 per cubic millimeter. The patient suffered an attack of severe epigastric pain necessitating morphine for its relief. This was thought to be due to mesenteric thromboses associated with the high platelet level. The following morning the platelets numbered 1,100,000 per cubic millimeter and another attack of severe epigastric pain occurred, associated with a rise in temperature to 103° F. and leukocytosis of 16,000. In the afternoon, there was a severe generalized convulsion starting on the right side and lasting several minutes. On the eighth day postoperatively the platelets were still 1,200,000 per cubic millimeter and two more severe convulsions occurred, each lasting a few minutes. Since it was felt that the high platelet level and intravascular thromboses might account for the convulsive seizures, an attempt was made to reduce the numbers of platelets by a deep x-ray treatment given over the chest to affect the largest amount of circulating blood. Following this there was only one mild attack of epigastric pain with fever and no further convulsions. On the eleventh postoperative day the platelet level was 800,000 per cubic millimeter and the following day 600,000 per cubic millimeter. At the time of discharge twenty-four days postoperatively the platelet level was 400,000 per cubic millimeter, the erythrocytes 5,400,000, hemoglobin 14 Gm. and reticulocytes 2 per cent.

The patient has had an uneventful course since discharge from the hospital one year ago, with no further changes in the blood as well as no recurrence of her previous complaints.

*Comment.*—In the family of this patient there was the suggestive history of recurrent mild jaundice suffered by the father but as so frequently occurs in adults with a mild degree of congenital hemolytic anemia, there had been very little interference with health or activity and no severe crises. In the child's case, however, the attacks had begun very early in life and had become increasingly frequent and severe from the third to the eleventh year of life. Special attention may be directed to the recurrence of deep yellow to orange urine and stool discoloration during the hemolytic crises. This has been particularly noted in children whose urobilin excretion is tremendously elevated as hemolysis occurs. In this patient about forty times the normal amounts of urobilin were being excreted by way of the urine and stools, a loss in blood pigments going hand in hand with the severity of the hemolysis and anemia which developed. Here again roentgenograms showed severe retardation in carpal development and bony growth and the long bones likewise showed expansion of the medullary substance at the expense of the cortical bone.

Following splenectomy there occurred one of the unfortunate but not rare complications of this operation. It has been pointed out by several observers that splenectomy is followed by a great rise in the levels of platelets in the peripheral circulation. Rosenthal<sup>15</sup> has followed such changes in patients with the splenic type of anemia and has related their extreme platelet elevations to the crises of fever and pain resulting from intravascular thromboses. In this child the platelets rose to over 1,000,000 per cubic millimeter at the end of the first week following operation, and severe epigastric pain, fever, and then generalized convulsions all pointed to the possibility of intravascular thrombosis associated with the very high platelet level. One method of reducing the levels of blood platelets that has been used in the past is deep x-ray therapy and in this instance such a treatment was given and was apparently effective, for the platelets fell to normal levels and remained so thereafter. The child suffered no further attacks of abdominal pain or convulsions. No method has as yet been developed

for preventing this platelet crisis following splenectomy or predicting the possibility of its occurrence. It must therefore be looked upon as a possible unfortunate complication which luckily, in our cases, has tended to be transitory and short in its duration.

**Case VI.**—An eight-year-old boy was referred to the hospital by his local physician because of recurrent attacks of feverishness followed by jaundice and pallor.

The family history was important in that the mother, a maternal uncle, and the maternal grandfather had had similar, though milder, attacks since early in life, but had never been seriously indisposed by their illness and had never required medical advice on this account.

**Past history:** in the first year of life the patient had had an attack of feverishness followed by yellowness of the skin and sclerae and moderate pallor but he had exhibited no failure of appetite nor loss of weight on this account. In his second year, the child suffered several times from "grippe" as judged by fever, abdominal pain, and vomiting, but following each such attack it was noted that he was once more jaundiced and pale and that this state lasted two to three weeks. From the third to the eighth years of life the boy had such attacks at least three to four times per year, becoming more severe and more prolonged and usually followed by anorexia and easy fatigue. Because of the increasing frequency and disability attending these attacks he had been unable to continue his schooling.

Physical examination revealed a very small underdeveloped and undernourished boy somewhat mentally apathetic. There was moderate icterus of the skin and sclerae and pallor of the mucous membranes. Small lymph nodes were palpable all over the body. The heart was enlarged 2 cm. outside the left nipple line and a loud systolic murmur was heard all over the precordium. The abdomen was protuberant with the liver palpable 4 fingerbreadths below the costal margin on the right and the spleen palpable 5 fingerbreadths below the costal margin and reaching to the umbilicus in the midline.

**Laboratory data:** red blood cells 2,600,000 per cubic millimeter; platelets 280,000 per cubic millimeter; stained smears of the blood revealed reticulocytes 22 per cent, moderate poikilocytosis, and a small globular type of erythrocyte. The icterus index was 40; fragility in hypotonic saline solutions: hemolysis beginning at 0.76 per cent and complete at 0.36 per cent. The urobilin in the urine and stools was markedly increased in quantity.

**Roentgenograms:** there was increased porosity of the bones of the extremities and the skull as well as increase in the size of the heart shadow. The carpal development was that of a child under five years (chronological age eight and one-half years).

**Course:** with all these confirmatory findings of congenital hemolytic anemia and the marked delay in development of the skeletal structures it was felt that splenectomy was definitely indicated. However, permission was refused by the parents because of their fear of any operative procedures and their feeling that the condition would improve with age as it had in the other mem-

bers of the family, suffering from the disease. The patient was therefore placed on a high iron and vitamin diet and given liver both parenterally and by mouth. There was some improvement in erythrocyte and hemoglobin levels. When seen six months after discharge from the hospital the patient related that there had been two other severe attacks of jaundice followed by pallor and extreme tiredness. Two years afterward, history revealed that the attacks were continuing unchanged in frequency or severity, necessitating one to two months' rest after each one and interfering with attendance at school. The blood showed no change from the measurements recorded at the time of hospitalization. Roentgenograms showed no development in the carpal bones and increasing porosity in the bones of the extremities and skull. In addition, the plates of the abdomen showed many small opaque bodies in the right upper quadrant, interpreted as gallstones. On careful questioning the child admitted that the abdominal pain which he frequently suffered now tended to radiate from the right side to the right scapular region and during one attack the jaundice had become much more severe than at any time previously and the stools had become clay-colored for a few days. Permission to operate was still refused by the parents.

*Comment.*—This child presents the most striking family history of any of our group of over 20 children with congenital hemolytic anemia, in that the disturbance has appeared through at least three generations, starting with his maternal grandfather. The supposition which so many laymen have that, because an adult has "outgrown" a disturbance, a child with the same disease will necessarily fare equally well is entirely erroneous and is well illustrated by the course of this boy's illness. Not only have his hemolytic crises become more frequent and more severe, but as the result of this chronic disease process his heart has become enlarged, and retardation in bone growth has occurred. The relatively infrequent childhood complication of cholelithiasis has here taken place. It is not unlikely that an attack of biliary obstruction due to gallstones will increase this child's difficulties at some future time and may make completely recovery from his disease very difficult.

#### DISCUSSION

The outstanding fact which appears from a study of these cases is that congenital hemolytic anemia which manifests its presence in childhood may not progress in as benign a fashion as it may in adult life. The younger the patient at the time

of the first crisis of hemolysis, the more severe the disturbance tends to become. Death may occur during an attack, even during the first, for the bone marrow of the young does not have as great an emergency store of erythrocytes and an hemolytic crisis may be quickly followed by all the symptoms of acute and fatal hemorrhage. The infant who is suffering from hemolytic anemia may not be able to afford to wait for a second crisis, before splenectomy need be performed.

As the child passes through succeeding attacks of hemolysis, jaundice and anemia, there appears evidence of disturbance in function of organs other than the hematopoietic-hemolytic system. The heart becomes enlarged, the valves insufficient and cardiac decompensation may occur. The growth of the skeletal structures is interfered with. Not only is stature small but the centers of ossification are delayed in appearance. In addition the bones tend to become wide but thin at the cortex. This is the result of the hypertrophy of the marrow tissue in an effort to keep up maximum erythrocyte production. In some cases there has even been a suspicion of retardation in mental development. Continued hyperbilirubinemia in unoperated cases may lead to the production of gallstones and the subsequent danger from biliary obstruction.

Early splenectomy for the infant or child with congenital hemolytic anemia is therefore indicated. Sometimes, it will be necessary as a life-saving measure. Splenectomy controls the tendency to crises of hemolysis and relieves the burden placed on the heart by the chronic and recurrently severe anemia. It likewise corrects the deranged metabolism which interferes with skeletal growth and proper bone structure.

One complication which follows splenectomy must be watched for. It consists of the building up of a tremendous platelet level within the first week or two following operation. This may be associated with evidences of intravascular thrombosis, manifesting itself in abdominal pain, fever, leukocytosis and in one of our cases, even convulsions. This "platelet crisis" usually subsides in a relatively short time.

## SUMMARY

Six cases of congenital hemolytic anemia occurring in infancy and in childhood are presented. They illustrate the variations in the disease as it manifests itself in this age group. It is emphasized that early diagnosis and prompt treatment by splenectomy are necessary since the disturbance is more acute and more severe the earlier it first appears. Death from anemia may occur in the first hemolytic crisis. Delay in treatment of the more chronic cases leads to cardiac hypertrophy and dilatation, retardation in skeletal growth and disturbance in bone structure. Likewise, cholelithiasis may develop. Splenectomy offers prompt and long-lasting relief from hemolytic crises and their attending icterus and anemia as well as from the cardiac disturbance and faulty bone growth.

## CLINIC OF DR. ELLIOTT P. JOSLIN

GEORGE F. BAKER CLINIC, NEW ENGLAND DEACONESS  
HOSPITAL

### PROTAMINE INSULIN—THE INSULIN FOR USE BY THE GENERAL PRACTITIONER FOR THE MAJORITY OF DIABETICS

PRACTICALLY all of us who have used protamine insulin have stated, and indeed, almost boasted, that we have tested protamine insulin with diabetics who were the severest of the severe and the most reliable. Perhaps this is as it should be, but the facts are that the great advantages of protamine insulin are for the many diabetics in the country and not for the few. Nobody knows how many diabetics there are in the United States or how many are mild, moderate or severe, but I suspect that there are in all between 400,000 and 500,000 individuals with diabetes, although some of them may not know they have it, that approximately 300,000 of them are mild cases, that 175,000 are moderately severe and this leaves only 25,000 who can be considered severe. Perhaps half of the mild cases can keep their diabetes controlled with a diet only moderately restricted, such as carbohydrate 150 Gm. and a reasonable amount of protein and fat, and it is because we can confidently say to the remaining 150,000 mild cases and the 175,000 moderately severe cases that their disease can be controlled with a small daily dose of this new protamine insulin and a diet which is but a whit more strict, that this great advance in diabetic therapy should be recognized and named for its discoverer, H. G. B. Zedern, M.D.

It is this factor which has raised the expectancy of the diabetic children from one year to thirty-two years and which has practically abolished coma, has more than

doubled the duration of the disease for all diabetics and, I believe, has advanced it for cases with onset in 1936 to an average duration of twenty years and quite likely twenty-five years, even though we handicap the patients under twenty years with those whose onset is above sixty years. The mere recital that in my group of diabetic doctors with onset between twenty-five and thirty-nine years the mortality is only one fourth that of my nondoctor diabetics, that only one doctor in the entire group of doctors has developed coma since 1924 and that of the doctors who have died the average age at death has been sixty-eight years, proves how much can be done in lessening mortality if the patient understands his disease. If regular insulin with its transient action has accomplished all this, how much more should be accomplished for the diabetic when under the prolonged action of protamine insulin.

Protamine insulin controls the diabetic for a whole day instead of for a six- to eight-hour period and the significance of this as yet we hardly grasp. With diabetes so much better controlled, what problems are we to meet with our diabetics in the future? Indeed, we hardly realize the possibilities for the change in the diabetic situation which protamine insulin has wrought. This was brought home to me the other day most emphatically by some figures which were placed at my disposal by Mr. Marks, working with Dr. Louis I. Dublin of the Metropolitan Life Insurance Company. I told Mr. Marks I felt sure arteriosclerosis was being deferred to some extent in our cases, because whereas Dr. Shields Warren has always found arteriosclerosis present in a diabetic of five years' duration, irrespective of age, now at autopsies this is by no means invariably true. This led Mr. Marks to compile the statistics of my own fatal cases of arteriosclerosis for two periods, and he was good enough to send me the following table (Table 1). Of course this can be improved in size numerically with time, but I think it shows quite plainly how the wind is blowing. Neither Mr. Marks nor I would claim too much for this table. We realize its deficiencies perfectly well, but it does bring out the point that the patients who die of arterio-sclero-si-

\* Prepared under the supervision of Mr. Herbert H. Marks of the Statistical Department of the Metropolitan Life Insurance Company.

† Includes deaths from chronic heart disease, cerebral hemorrhage, chronic nephritis, arteriosclerosis, gangrene, etc.

whether general or local, in the heart or legs, today are surviving diabetes for a greater number of years than before, and thus dying older, or, in other words, that the development of arteriosclerosis is being deferred. I am sure that all who look at this table can supplement it, and it is most desirable that similar data should be reported from the many diabetic clinics which exist in this country. If we can say with assurance to our patients that already with the use of regular insulin, we have seen not only complications such as coma and carbuncles reduced, but even premature old age deferred, and that now there is every reason to expect that with protamine insulin these favorable changes will be promoted, it will promote a zeal for the thorough treatment of diabetes throughout the country which is almost incalculable.

The type of protamine insulin which will go on the market (I am quite sure I am correctly informed) is protamine zinc insulin of U-40 strength. From our tests with the various

types of protamine insulin with about 700 patients, my colleagues and I can state unquestionably that protamine zinc insulin is the best we have had. Protamine insulin, fresh from Dr. Hagedorn, later from the Eli Lilly Co., and subsequently from the E. R. Squibbs and Sons Co., was a great comfort to the children in relieving them of multiple injections. Protamine calcium insulin worked still better and indeed excellently last summer with 65 girls at the Clara Barton diabetic camp. Miss Winterbottom, who has had charge of the camp for three years and thus has watched diabetic girls each summer, stated emphatically that protamine calcium insulin worked better than the regular insulin, that reactions were less frequent, that the reactions were less severe and, in general, that the children who had protamine calcium insulin wanted to continue it and the 50 or 60 who did not have it were anxious to get it. However, at our other diabetic camp, the Prendergast Preventorium, where a group of boys and girls volunteered to undergo tests with protamine calcium insulin and protamine zinc insulin, Dr. Priscilla White was able to show with the help of Dr. Schott that protamine zinc insulin was released more slowly and therefore acted a little less quickly and for a more prolonged period. Incidentally, she was able to test protamine zinc insulin produced by two of the larger pharmaceutical houses and to demonstrate that the products furnished were essentially uniform in action, which should be reassuring to all doctors.

Protamine zinc insulin will keep. I have been definitely assured that there is little if any doubt that it will last for six months with a deterioration of only 10 per cent, even though, contrary to good practice, it is not in a refrigerator all the time. Furthermore, I understand that even after the protamine has been mixed with the insulin, as in the combined preparation which is to be dispensed in a single vial, the loss of potency is not expected to be material. At this moment we are just beginning the use of this new preparation. Certainly the addition of the zinc has preserved the permanency of the flocculency of the precipitate to a remarkable degree.

Protamine zinc insulin can be used with syringes which have been sterilized with alcohol so that patients who have adopted this method of sterilization can continue it and need not change to sterilization and drying of their syringes with heat.

If regular insulin and protamine zinc insulin are given the one after the other with the same syringe, the regular insulin should be given first. Should the protamine insulin precede the regular insulin in the syringe, enough of the protamine might remain on the surface of the same to change the regular insulin to protamine insulin and thus eliminate its specific action.

The possibility for the use of protamine insulin in out-patient clinics has been emphasized by several writers, but in general its efficacy has been stressed with the responsible and pedigreed diabetic. What I want to bring out in this clinic is that protamine zinc insulin is the kind of insulin which the general practitioner and the majority of diabetics will find simplest and safest, and therefore I will report 5 cases which illustrate this one point and rest content if I make this plain.

**Case I.**—The last patient seen in the late afternoon of August 25 was a colored man, George —, 14815, thirty-four years old, with 4.2 per cent sugar, no diacetic acid. His weight had dropped from 140 to 126 pounds dressed, but physical examination presented no other striking abnormalities. I tried to get him into the hospital, but failed and so told him to take a slice of bread and an orange at each meal, and during the twenty-four hours  $\frac{1}{2}$  pint of milk and cream with a moderate amount of butter, a little cereal, four portions of 5 and 10 per cent vegetables, an egg and bacon if he could get it for breakfast, and for the other two meals a moderate quantity of meat and fish, and lastly I gave him 10 units of protamine zinc insulin. The next morning I saw him at the hospital at the Diabetic Class and he was given 10 units of protamine zinc insulin and when he returned the next day—the 27th—10 units of protamine zinc insulin and, still no hospital vacancy, I decided not to have him enter anyway, despite the fact the urine contained in 3 specimens 3.6, 2.6 and 6 per cent respectively, because I felt so much confidence that with 10 units of protamine zinc insulin the next day in one dose he would begin to clear up. And he did, because the specimens showed 4, 0.3, 0.4 and 2.8 per cent respectively. By the late afternoon of September 1, the urine contained 0.2 per cent sugar and the blood sugar was 0.12 (120 mg.) per cent. Upon September 2 the urine was sugar-free, blood sugar 0.06 (60 mg.) per cent, necessitating the reduction of insulin to 24 units, and weight 137 $\frac{1}{2}$  pounds dressed—

a gain of  $12\frac{1}{2}$  pounds in a month. Upon October 27 no glycosuria, blood sugar 0.07 (70 mg.) per cent before lunch and weight 142 pounds. And this negro did not lose a single full day's work from his job as a draftsman and in fact was only seen nine times for short visits.

I must in fairness add he was a graduate of the Massachusetts Institute of Technology.

**Case II.**—Blair W., 14484, already reported elsewhere, came to the office on the afternoon of April 9, 1936, within an hour of glycosuria having been discovered, showing 7.3 per cent urinary sugar and a blood sugar of 0.51 (510 mg.) per cent. Entering the hospital, the glycosuria was 10.4 per cent the following morning. He then was given 30 units of protamine insulin and for the next four days 50 units daily, and became sugar-free. Thereafter, for each of two days he received 46 units, the next day 40 units and was discharged with a diet of carbohydrate 210 Gm., protein 75 Gm., and fat 88 Gm. Upon May 30 he was sugar-free, taking 24 units of protamine insulin; upon July 31 he was likewise sugar-free and the blood sugar was 0.13 (130 mg.) per cent, capillary blood at three hours after lunch, with 16 units of protamine insulin daily; and upon November 15 he is still sugar-free, but requires only 8 units of protamine insulin in the twenty-four hours.

Of course, any one who has seen many cases of diabetes realizes that a child, whose treatment is begun, as in the case of Blair, shortly after the onset of the disease, will do surprisingly well. However, at the moment, I do not recall any patient whose diabetes has been as easily controlled as in this case. At no time during his illness has Blair received an injection of insulin more than once in twenty-four hours.

**Case III.**—A minister's widow, 7245, who came to me like Blair presumably within two weeks of the onset of her disease, on September 7, 1928, showing 6.9 per cent sugar and a blood sugar of 0.44 (440 mg.) per cent, did quite well with regular insulin. However, it was a bore to take 10 units of insulin in the morning and 6 units at night and so, on May 6, 1936, she was changed to 16 units of protamine insulin once daily, and I submit (Table 2) her reports sent in for the following four days, the test being made at rising, noon, afternoon and upon retiring.

Gradually reports came in at less and less frequent intervals but now are submitted once a month for analyses made on one day a week. These are also shown in Table 3.

The records of this patient not only show how much simpler modern treatment of diabetes is, but they indicate that a patient

living a reasonably uniform life can get along very well, making tests for sugar once a week.

Case IV.—Since January 24, 1931, I have taken care of Mrs. D., 9773, whose diabetes was mild, showing only 0.1 per cent sugar and a blood sugar of 618 (180 mg.) per cent upon a fairly liberal diet. Somewhat later she required 8 or 10 units of insulin once a day to control her diabetes, but in January, 1934, at the age of seventy-one years, she developed pneumonia and, despite the increasing severity of her diabetes which necessitated a total of 72

units daily administered in 6 doses, she finally recovered. Realizing the critical nature of her illness, she was treated as a surgical diabetic and given glucose and salt solution subcutaneously or intravenously so that always the carbohydrate in the diet for the twenty-four hours was at least 150 and sometimes even 200 Gm. daily. Notwithstanding troublesome diarrhea, nausea, and vomiting the disease terminated by lysis at the end of eleven days. Convalescence was uninterrupted. The following summer she journeyed to Lausanne, but the next summer she felt so sprightly that she chose Biarritz and returned taking 10 units of insulin.

By September and October, 1936, not only were two small injections daily becoming annoying, but various cardiac symptoms developed. Regular insulin was then replaced with a single dose of protamine insulin and since that time the patient has been insistent that the use of protamine insulin has relieved her of cardiac discomfort. At any rate she is much more comfortable and the diabetes is equally well, although not absolutely, controlled. The urine contained 0.2 per cent sugar and the blood sugar in the late forenoon, February 1, 1937, was 0.16 (160 mg.) per cent.

**Case V.**—Mrs. R.'s (10998) diabetes developed in April, 1932, at which time I found 3.2 per cent glycosuria and a blood sugar of 0.39 (390 mg.) per cent. She became sugar-free with insulin 12–0–12 units, eventually omitted it and was sugar-free on June 8, 1933, with a blood sugar of 0.11 (110 mg.) per cent, retaining her first weight of 153 pounds. Upon October 13, 1936, she returned with 5.4 per cent glycosuria and a blood sugar of 0.32 (320 mg.) per cent, and without insulin. She was given 20 units of protamine insulin. Upon October 17, the specimens contained 0.3 per cent sugar before breakfast and the office specimen contained 2.8 per cent sugar. Continuing on the same insulin, on October 23 the fasting specimen was sugar-free and the office specimen contained 1.8 per cent sugar, the blood sugar was 0.25 (250 mg.) per cent. One week later not only the fasting specimen was sugar-free but the single specimen contained but 0.1 per cent sugar and the blood sugar was 0.14 (140 mg.) per cent, while taking 24 units of protamine insulin.

I did not see her again until November 13 when she returned in excellent condition, urine sugar-free and capillary blood sugar 0.11 (110 mg.) per cent, at three hours after lunch, protamine insulin 20 units.

As Mrs. R. was born on October 15, 1856, her last visit was made when she was eighty years of age, thus presenting a contrast to Blair, who was eleven years old, although I might add that our youngest patient to take protamine insulin began at the age of two years.

In the last few weeks various medical societies have been kind enough to ask me to talk about protamine zinc insulin, and what has impressed me most in watching these audiences has been the change in the expression on the faces of those present when I have had a child on the platform and said to him, "George, look over these doctors and let us pretend that

this group would treat your diabetes by giving you insulin four times a day, that group three times a day, the group of doctors over there two times a day, but these doctors right here would treat you just as well as the others but would give you insulin only once a day. Which doctors in the audience, George, do you think you would like to have take care of you?" George, being a bright boy, like most diabetic boys, you cannot doubt his instant answer.

## CLINIC OF DR. ALEXANDER MARBLE

GEORGE F. BAKER CLINIC, ELLIOTT P. JOSLIN, M. D., MEDICAL  
DIRECTOR, NEW ENGLAND DEACONESS HOSPITAL

---

### TREATMENT OF DIABETES MELLITUS IN THE PRESENCE OF A HIGH OR LOW THRESHOLD FOR SUGAR

#### GENERAL CONSIDERATIONS

It is generally accepted that the glomeruli of the kidney permit the passage into the tubules of a fluid, the composition of which is almost the same as that of the blood plasma except that proteins and fats normally are not allowed to pass through the renal filter. As this glomerular filtrate passes along the renal tubules, it is modified in various ways among which is the reabsorption of certain "threshold" substances of value in the body, as sugar, chloride, sodium, calcium and bicarbonate. Substances which in the normal individual are reabsorbed completely or almost completely are spoken of as possessing a high threshold. Among these is sugar, *i. e.*, glucose, for which the average threshold is often stated to be about 0.16 to 0.18 per cent. Since in normal persons the blood sugar is below this level, ordinarily all of the sugar in the glomerular filtrate is reabsorbed except for very tiny quantities of glucose excreted by some individuals along with small amounts of non-glucose reducing substances.<sup>1</sup> If the blood sugar rises above this level or if the threshold is lowered, sugar appears in the urine in quantities easily detectable by the usual copper reduction methods.

#### THE NORMAL RENAL THRESHOLD FOR SUGAR

Numerous studies have been made in order to determine the normal renal threshold for sugar and the values cited above

are merely those commonly quoted. It is generally conceded now that the renal threshold is largely an individual matter and varies widely from person to person. In interpreting the reports in the literature one must take into consideration the methods of study employed; particularly as regards—

1. The type of blood used, *i. e.*, whether arterial (capillary) or venous.

2. The blood sugar method used, with attention to the closeness with which the values obtained approach the "true sugar" content of the blood. Methods which eliminate in so far as possible nonglucose reducing substances are to be preferred.

3. The method of determining the threshold. Four methods have commonly been used:<sup>2</sup>

- (a) On different days simultaneous tests of blood and urine are made with the patient in the fasting state, hoping by this procedure to obtain some urine specimens with and some without sugar. From these data then conclusions can be drawn regarding the threshold.

- (b) A patient with glycosuria is kept in the fasting state. When frequent tests indicate that the urinary sugar is becoming slight in amount, simultaneous tests of blood and urine are made at frequent intervals until several sugar-free urine specimens have been obtained. The blood sugar value at the point of disappearance of urinary sugar is taken as the threshold figure.<sup>3</sup> One may use this method in patients with renal glycosuria and in cases with a very low threshold, a single dose of insulin may be given to reduce the blood sugar lower than could be accomplished by fasting alone.

- (c) Starting with a sugar-free urine one gives sufficient carbohydrate to cause glycosuria. At frequent intervals tests of blood and urine are made and note taken of the blood sugar level at which sugar appears in, and (on the descending limb of the curve) disappears from, the urine. Hatlehol states that Frank<sup>4</sup> was the first to note that the threshold of appearance often is not the same as the threshold of disappearance. Once glycosuria has been produced by virtue of sufficient hyper-

glycemia, the urinary sugar persists for a variable period after the blood sugar has fallen below the value initially necessary to produce glycosuria. The cause of this lag is not entirely clear. Sherrill and MacKay<sup>5</sup> consider that it is due to the "dead space" of the kidney and ureter.

The following glucose tolerance data obtained on November 16, 1936, on Mr. W. M., Case 14997, a fifty-nine-year-old Jewish clothing salesman without typical diabetic symptoms illustrate the type of response under discussion:

Time.	Urine.		Blood sugar (venous), mg. per 100 cc.
	Volume, cc.	Sugar, per cent.	
Fasting.....	50	0	0.15
100 grams of glucose by mouth			
30 minutes after glucose....	16	0.2	0.25
60 minutes after glucose....	24	3.0	0.15
120 minutes after glucose....	65	3.2	0.11
180 minutes after glucose....	80	2.4	0.08

(d) Two blood sugar curves are obtained on different days, one with an amount of carbohydrate small enough as not to provoke glycosuria and the other sufficiently large as to cause urinary sugar to appear. Blood sugar estimations as often as every five minutes are desirable and tests of the urine are made at ten- to twenty-minute intervals. The renal threshold for sugar is known to lie between the highest points on the two curves. More than two curves may be necessary to determine the threshold with accuracy.<sup>6</sup>

It has not seemed profitable to attempt a complete review of the literature concerning the average normal threshold. From a glance at Table 1 in which are summarized the results of 10 investigations, it will be readily seen that a wide range of values (0.05 to 0.39 per cent) has been reported. It is doubtful, however, if all of the subjects used could be classed as truly normal.

TABLE 1

SUMMARY OF VALUES REPORTED FOR THE RENAL THRESHOLD FOR SUGAR  
IN NORMAL INDIVIDUALS

Author.	Year.	Number of subjects.	Type of blood.	Blood sugar method.	Range of values, per cent.
Jacobsen <sup>7</sup> .....	1913	16	Capillary.	Bang.	0.17-0.18
Hamman and Hirschman <sup>8</sup> .	1917	6	Venous.	Lewis-Benedict.	0.12-0.18
Goto and Kuno <sup>9</sup> .....	1921	12	Venous (plasma).	Meyers-Bailey.	0.12-0.18
John <sup>10</sup> .....	1922	35 (nondiabetics)	Venous.	Myer-Benedict.	0.05-0.23
Höst <sup>11</sup> .....	1923	25	Capillary.	Hagedorn-Jensen.	0.11-0.22
MacKay <sup>12</sup> .....	1927	44	Not stated.	Not stated.	below 0.13- above 0.39
Glassberg <sup>13</sup> .....	1931	51 (nondiabetics)	Capillary.	Somogyi.	below 0.10- above 0.25
Himsworth <sup>14</sup> .....	1931	11	Capillary.	MacLean.	0.13-0.25
Campbell, Osgood and Haskins <sup>15</sup> .....	1932	24	Venous.	Somogyi-Shaffer-Hartman.	0.10-0.23
Sherrill and MacKay <sup>16</sup> ....	1935	11	Capillary.	Somogyi-Shaffer-Hartman.	0.08-0.16

\*In all of the studies to which reference is made in Table 1, the method employed was that outlined above under the heading (c) except in the studies of MacKay in which the blood and urine were examined before, during and after surgical anesthesia. Goto and Kuno, John, Höst (in most of his experiments), and Glassberg took as the threshold the level of blood sugar at which sugar first appeared in the urine; Hamman and Hirschman considered not only the level of appearance of glycosuria but also that of disappearance; Campbell, Osgood and Haskins noted the level of blood sugar at the time of disappearance of urinary sugar; Sherrill and MacKay did likewise except that they gave glucose intravenously rather than orally as did all other workers (except Höst in certain studies) mentioned. John's<sup>16</sup> larger series of 833 renal threshold estimations is not included because it is difficult to decide how many of his subjects can be classed as "normal." He concluded that the actual average renal threshold was "somewhere near 150 mgm."

Various factors may influence the renal threshold aside from the wide individual variation described above. Among these is the age of the individual: John<sup>16</sup> found the average threshold among 33 patients under twenty years of age to be relatively high, 174 mg. Conditions of impaired renal function may raise it; it may be elevated in nephritis<sup>8</sup> and furthermore in the carrying out of tests on individuals, normal or otherwise, the degree of renal activity as reflected in the output of urine may greatly influence the results.<sup>5</sup> It may be elevated in poisoning with certain narcotics as morphine<sup>17</sup> and in certain disease conditions as hypertension, syphilis, obesity, acromegaly, and particularly arthritis and diabetes.<sup>16</sup> It may be lowered in pregnancy or poisoning with phloridzin<sup>18</sup> or certain metals.<sup>4</sup> It is low in the condition known as renal glycosuria which undoubtedly is simply the reflection of a very low threshold.

Major<sup>19</sup> in a study of diabetic patients with hyperglycemia but without glycosuria found that the high values for blood sugar were due to a fermentable sugar, presumably glucose, and not to any nonexcretable substance.

Faber<sup>20</sup> believes that the renal threshold is constant for any individual throughout life. Other investigators, as Glassberg,<sup>13</sup> however, have reported cases in which the threshold seemed to vary from time to time. Robinson and coworkers<sup>21</sup> from studies involving the giving of 7.5 to 20 Gm. of glucose intravenously, found that the level of appearance of sugar in the urine was constant for an individual when the same dose was given but varied with different people. With the same person it varied with the dose. They suggest that in cases of hyperglycemic glycosuria "some element in the phosphorylation mechanism, such as the store of phosphate or of enzyme in the tubular membranes," becomes exhausted.

#### RENAL THRESHOLD IN DIABETES

Thirty years ago Liefmann and Stern<sup>22</sup> from a study of 8 cases concluded that the renal threshold tends to be low in cases of diabetes with recent onset and to rise as the disease

progresses. A somewhat similar view was held by von Noorden<sup>23</sup> (particularly in cases of diabetes complicated by nephritis and hypertension), by Williams and Humphreys<sup>24</sup> and by Allen and Wishart<sup>17</sup> (from dogs with experimental diabetes). On the other hand, in a study of 11 patients Hamman and Hirschman<sup>8</sup> found, on the average, higher threshold values in cases of mild, as compared with those of advanced, diabetes. Likewise, Petré<sup>25</sup> reported that the highest values were obtained among the youngest patients and among those with diabetes of recent onset. As opposed to these conflicting reports, other workers have stated that, as with normal individuals, the renal threshold in diabetic patients is an individual matter, varying from person to person, and is not related to the age or sex of the patient, the duration of the diabetes, or the severity of the disease. This was the conclusion of Jacobsen,<sup>7</sup> Faber and Norgaard,<sup>3</sup> Faber and Hansen,<sup>20</sup> Hatlehol<sup>2</sup> and Sakaguchi *et al.*<sup>27</sup> In their recent careful study Sherrill and MacKay<sup>7</sup> found an average value of 149 mg. per cent for their diabetic group as compared with that of 128 mg. for the nondiabetic group (capillary blood, Somogyi-Shaffer-Hartman method). This tendency to a higher threshold in diabetes was found also by John<sup>10</sup> who reported that among 54 diabetics the average renal threshold was at 217 mg. per 100 cc. (venous blood; Myer-Benedict method). Thresholds below 180 mg. were found in 27.7 per cent of cases and above 180 mg. in 72.2 per cent. Among 833 patients of various types, only in arthritis and diabetes was the average threshold higher than the commonly quoted value of 180 mg.

On the whole the available data seem to indicate that the renal threshold tends to be higher in diabetic persons than in normal individuals but that in both groups it varies widely and is an individual matter.

#### TREATMENT OF DIABETES IN THE PRESENCE OF A HIGH THRESHOLD

Leaving aside the question as to basis or cause, it is a fact that one not infrequently encounters diabetic patients, usually

middle-aged or elderly persons, who possess a high renal threshold (0.20 per cent or above) for sugar. Often these patients have considerable generalized arteriosclerosis with or without hypertension and often have some degree of chronic nephritis. The question then arises: should an attempt be made by giving insulin (or more insulin) to lower the blood sugar below the level at which glycosuria entirely disappears? Or should one be content with a sugar-free urine, regardless of the level of the blood sugar?

Using regular, quickly acting insulin, the attempt to maintain a normal or nearly normal blood sugar in such patients has certain drawbacks: (1) these patients are usually insulin-insensitive and sizable doses are often required to accomplish the desired effect; (2) without blood sugar determinations at intervals, it is difficult—with improvement in the condition of the patient—to foresee overdosage and consequent hypoglycemia with its deleterious action in a patient perhaps with coronary sclerosis; (3) usually little or no immediate subjective improvement is noted and one wonders whether the inconvenience and expense of daily hypodermic injections are worth while.

Because of these considerations, in our practice we have in the past ordinarily not insisted upon the use of insulin or extra insulin in patients of this type provided the urine was untotally sugar-free and no demonstrable acidosis was present. This was not, however, because of any belief that the hyperglycemia was beneficial. Now that protamine insulin has made treatment so convenient and so safe, we are beginning to use it more and more in such patients in an attempt to keep the blood sugar throughout the entire day within relatively normal limits (below 2 per cent). We have observed no ill effects from establishing a lower average glycemic level and it seems probable that any tendency to acidosis should be avoided. It is surprising how large doses of protamine insulin can be given to these elderly patients with no sign of toxicity. Thus Mrs. J. P. Case 14,375, aged fifty-eight years, has been on this treatment for months' duration, was essentially sugar-

free both with and without 40 units of protamine insulin daily. On admission to the hospital on December 29, 1935, with a deep infection of the right foot her urine had contained 2.4 per cent sugar and the blood sugar at 8:30 P. M. was 0.27 per cent. See Table 2 for relevant data.

TABLE 2

MRS. J. P., CASE 14,375, URINE AND BLOOD FINDINGS WITH AND WITHOUT INSULIN. DIET THROUGHOUT CONSISTED OF CARBOHYDRATE 140 GM., PROTEIN 60 GM., FAT 75 GM., 1475 CALORIES DAILY

\* Regular insulin.

† Includes 20 units regular insulin.

It is a well-recognized clinical fact that patients with impairment of kidney function, particularly those with uremia or "renal block," may exhibit a raising of the renal threshold for sugar. The 3 cases of nephritis studied by Hamman and Hirschman<sup>8</sup> had threshold values higher than the general average. John's<sup>16</sup> series included no nephritics classified as such but it is interesting to note that of 49 cases with hypertension, the average threshold was 165 which is considerably above the figure of 149 for the entire group studied. Below are given in abstract form data regarding such a patient.

Mrs. L. M. S., Case 6082, fifty-one years old, with diabetes of four years' duration, was admitted to the New England Deaconess Hospital on May 16.

1927, in diabetic coma. There was infection and gangrene of the left foot with lymphangitis extending one third of the way to the knee. There was, however, on admission little or no fever. In Table 3 are listed the findings as regards the blood and urine.

TABLE 3

			0	0					

This patient was in the hospital for approximately a month and during most of this time had marked fever despite the fact that a guillotine amputation through the left lower leg on the day after admission removed the infected foot. The blood nonprotein nitrogen fell but never to below 65 mg. per 100 cc. She died on June 18, 1927, and at autopsy an empyema on the left and an abscess of the anterior mediastinum were found. The kidneys showed "early vascular nephritis."

Treatment in such acute cases is obviously difficult. One's chief efforts should be directed to measures designed to relieve the kidney failure with parenteral fluid, glucose and other treatment indicated, because, lacking in this, control of the blood sugar will be of no avail. However, a conscientious attempt should be made to keep the blood sugar within satisfactory limits (below 0.20 per cent). To do this, frequent determinations of the blood sugar, at intervals of two to four hours, are necessary since obviously tests of the urine, if obtained, are of no assistance. Large doses of insulin may be

necessary and may be given according to some such outline as that below:

1. Determine (capillary) blood sugar every four hours.
2. If blood sugar 0.50 or above, give 50 units.  
0.40 or above, give 40 units.  
0.30 or above, give 30 units.  
0.20 or above, give 20 units.  
below 0.20, give no insulin.

Such a schedule will, of course, vary from patient to patient but may serve as a type. As one learns more about its use, it is likely that large doses of protamine insulin may be valuable in this situation.

The cause of the elevated renal threshold in such cases is not understood but probably lies in some damage to the renal filter resulting in decreased activity with lessened volume of glomerular filtrate. The high blood sugar values obtained may be due in small part to the reducing effect on copper solutions of the large amount of nonprotein nitrogen substances in the blood, but this is not a large factor.

Before leaving the subject of the high renal threshold, it may be well to point out that if one insists, and rightly so, upon the presence of sugar in the urine in order to make the diagnosis of diabetes, then in certain individuals without glycosuria a definitely elevated blood sugar, and hence a high renal threshold, may not signify diabetes. In some patients with arthritis, for example, Nissen<sup>28</sup> has shown that definitely abnormal sugar tolerance curves—with little or no glycosuria—may be obtained despite the entire lack of symptoms or signs of diabetes or a progression toward it over a period of years.

#### TREATMENT OF DIABETES IN THE PRESENCE OF A LOW RENAL THRESHOLD

With certain diabetic patients as with normal individuals the renal threshold for sugar is low.<sup>29</sup> Such a patient is Case 8471, Miss J. E. C., aged forty-nine years, with diabetes of ten years' duration. Her renal threshold for sugar has not been accurately determined, but as Table 4 indicates, it is so

TABLE 4

MISS J. E. C., CASE 8471, DIABETES IN A PATIENT WITH A LOW RENAL THRESHOLD. THE DIET THROUGHOUT CONSISTED OF CARBOHYDRATE 166 GM., PROTEIN 90 GM., FAT 88-123 GM. DAILY

Date 1935.	Urine—24-hr. amount specimen.				Blood sugar, per cent.	Insulin.	
	Vol. cc.	Diacetic acid.	Sugar, per cent.	Total Gm.		Units.	Time.

low that if the insulin dosage is increased in an attempt to secure a sugar-free urine, hypoglycemic attacks occur in the presence of glycosuria. Obviously the sensible plan of treatment in such a patient is to allow a basic amount of glycosuria, as evidenced, say, by a green test with Benedict's solution.

Pregnancy lowers the renal threshold in the diabetic as well as in the normal person. This becomes manifest in the third trimester principally and the sugar excreted during this period is almost entirely true glucose. Treatment must be planned so as to allow slight glycosuria in order to avoid hypoglycemic attacks. Frequent blood sugar estimations are desirable, if not imperative, in order to direct treatment intelligently. Following delivery or the termination of the pregnancy, the renal threshold characteristic for that individual is resumed.

An important practical point in the care of any patient with glycosuria is the establishing of the correct diagnosis by blood sugar determinations or by a formal glucose tolerance test, if necessary. Otherwise diabetic treatment with diet and perhaps insulin may be imposed on an individual who because of a low renal threshold has a benign glycosuria. The following is a case in point:

Miss H. O., Case 4534, Jewish, was brought for treatment on April 6, 1925, being at that time three and one-half years of age. Sugar had been found in her urine on March 15, 1925, following an attack of tonsillitis during which her temperature had risen as high as 104° F. She spent three weeks at the New England Deaconess Hospital at that time. The admission specimen of urine contained 3 per cent sugar and subsequent daily analyses of the twenty-four-hour amount specimens showed constantly small amounts of sugar which became less, but never entirely disappeared, on treatment with diet and small doses of insulin. Because of her age, no blood sugar estimations were made; at this time capillary blood sugar estimations were not in general use.

Her parents were faithful in treatment and followed carefully the directions as to the restricted diet and insulin. She did well and in May, 1926, at the time of a tonsillectomy was excreting from 1 to 8 Gm. of sugar in twenty-four hours while receiving a diet of carbohydrate 52 Gm., protein 42 Gm. and fat 63 Gm. and from 8 to 18 units of insulin a day. Three capillary blood sugar values at this time were 0.07, 0.08 and 0.08 per cent respectively. On July 20, 1927, a capillary blood sugar of 0.21 per cent at 2 P. M. was recorded and at the time seemed to fit in with the diagnosis of diabetes. Study of her record in retrospect, however, shows this postprandial value to be the highest ever obtained in the eleven years of observation.

When seen in April, 1934, it was noted that on a diet which totaled as much as carbohydrate 194 Gm., protein 74 Gm. and fat 56 Gm. and with 10 units of insulin twice daily, all blood sugar values, either before or after meals, were normal. Furthermore on a "house diet" with sugar, glycosuria was no more pronounced even though insulin was entirely omitted. Consequently a formal sugar tolerance test using 75 Gm. of sucrose by mouth was carried out which yielded normal blood sugar values despite constant glycosuria throughout the test. The diagnosis of renal glycosuria was made. Insulin was discontinued and strict dietary treatment no longer advised. To date the patient has remained well and is developing normally.

Fortunately this patient suffered no permanent injury because of the enforcing of the diabetic regimen for eleven years. She grew satisfactorily and is in good health. However, much inconvenience was caused to her and her parents and the case serves well to illustrate the importance of careful blood studies in all patients and particularly in those in whom glycosuria persists despite normal values for blood sugar as obtained on random specimens.

### COMMENT

Experience teaches that most of the cases of diabetes reputed to be extraordinary in this or that respect, turn out on closer study to be straightforward in their course. Often laboratory errors have contributed to the confusion or correlation has been attempted between urine voided at one time and blood withdrawn hours or even days before or after. It is surprising how often hospitalization for a few days with opportunity for careful study as to complications, for con-

trolled conditions as to diet, insulin and activity and for supervision of laboratory work will clear up a confusing and supposedly unusual situation. The treatment of diabetes in the presence of a high or low threshold is usually not difficult if the patient has been carefully studied and a course of procedure well planned.

## CLINIC OF DR. HOWARD F. ROOT

GEORGE F. BAKER CLINIC, ELLIOTT P. JOSLIN, M. D., MEDICAL  
DIRECTOR, NEW ENGLAND DEACONESS HOSPITAL

---

### TRAUMA, PHYSICAL AND PSYCHIC, IN RELATION TO DIABETES

**Introduction.**—The relationship of trauma to diabetes, either as a cause of diabetes, or as a complication of existing diabetes, has long been a matter not merely of discussion but of real clinical and scientific importance. In recent years the frequency of accident insurance policies among the population of the United States and the increasing tendency to utilize the courts have resulted in the question being raised more and more frequently before judge and jury.

**Definition.**—Ordinarily, by trauma we mean a physical injury or wound produced by contact with some external object or objects. It may be accidental, unexpected, or a usual accompaniment of the activity of the subject, as in warfare. Psychic trauma is "an emotional shock that makes a lasting impression upon the mind, especially the subconscious mind" (Dorland). Trauma may be mild or severe. It may be sudden and of short duration, or of gradual onset and long duration. The effects of trauma may be direct or indirect. Thus, as a result of an injury which requires the patient to remain in bed for a long period, disturbance of the usual habits of living, including even the diet and the daily exercise, occurs. Infections at the site of trauma may introduce a totally unexpected and important factor.

**Nature of Diabetes.**—In considering the etiologic relationship of trauma to diabetes, one must bear in mind the great

frequency and universal character of diabetes. It is not merely the fact that there are in the population today 500,000 persons with diabetes in this country, and that another 2,500,000 will develop diabetes before they die, but that in all probability one fourth of the population are carriers of the tendency to diabetes which they may transmit to their own offspring. We have no way at present of selecting those destined to become the diabetics of tomorrow and the next year. In this large number the vast majority develop diabetes not at or near the time of trauma of any sort, but characteristically develop it at a time of unusually good health. The adults state usually that their weight was at maximum. The mothers of the children state usually that the child was never better than when the characteristic polyuria and polydipsia began to appear. The common precipitating factors in diabetes are well known. In adult life, obesity immediately precedes the onset of diabetes in fully 75 per cent of the cases; and this obesity frequently follows a period of months or years, in which time the habits of living have been changed notably by the reduction of the amount of muscular exercise. The pathology of diabetes is well known. Only a single method has been found so far by which diabetes can be constantly produced and that is by injury or removal of the pancreas. Pathologic observations from the time of Cawley to the present have clearly shown that the pathology of diabetes centers in the pancreas. It is true that the brilliant discovery by Claude Bernard in 1849, that glycosuria could be produced by puncture with a needle of the floor of the fourth ventricle, diverted the attention of the scientific world from the pancreas and has left as a direct result the impression that a direct part is played by some lesion in the brain upon the etiology of diabetes. Physiologic experimentation shows clearly that there is a direct innervation of the pancreas with connection to the brain and notably through the hypothalamus. Houssay abated the severity of diabetes in the depancreatized dog by removing the pituitary and Long showed that in the cat this effect depended upon the adrenal glands.

The relations of the nuclei at the base of the brain and of the higher centers to the carbohydrate metabolism are being carefully studied. It is becoming more and more clear that certain groups of cells in the central gray matter along the sylvian aqueduct and in the hypothalamus are important regulators of the autonomic nervous system, as pointed out in the review by J. C. White.<sup>1</sup> Davis, Cleveland, and Ingram<sup>2</sup> have emphasized the close relation between the hypothalamus and the pituitary. It is very difficult to tell which functions belong to the one or to the other. However, with the Horsley-Clarke stereotaxic instrument they were able to place accurate lesions in the hypothalamus and they found that under these circumstances complete removal of the pancreas was no longer followed by diabetes mellitus. The effect then was practically the same as if the pituitary had been removed as Houssay had done. Thus, when this pathway had been cut, stimulation of the superior cervical sympathetic ganglia no longer will produce hyperglycemia and glycosuria. It, therefore, appears that the hypothalamus exerts nervous control over the anterior lobe of the pituitary which may be quite important in the regulation of the carbohydrate metabolism. That the level of the blood sugar exerts the controlling influence upon the activity of the islands of Langerhans, however, seems generally agreed. It is a long leap from temporary glycosuria produced by trauma of the brain to clinical diabetes with its manifold variations, and its many complications.

**Degree of Trauma.**—In order that the trauma shall cause diabetes it must result in very grave damage to the pancreas. The severity of the damage may be judged by the fact that experimentally one can remove certainly three fourths and sometimes nine tenths of the pancreas without diabetes resulting. Ordinarily, a trauma so severe as to cause such an injury to the pancreas would be likely to cause death itself. Only rare cases may be found in literature which fulfill these requirements. It should theoretically be certain that the patient did not have diabetes before the accident occurred. If this proof were to be scientifically accurate, it should consist not

merely of an urine test made recently, but actually blood sugar analyses and even a glucose tolerance test done within an hour of the accident!!

A teamster, thirty-two years old, described by Professor H. Gideon Wells in 1922, fell from his wagon while intoxicated, and the wheels passed over his body. At the hospital 4 fractured ribs on the left side with subcutaneous emphysema were found. In twelve days he left the hospital in apparently good condition. However, he returned in four months with the history from his family that shortly after his discharge he had developed certain mental symptoms, great thirst, pruritus, jacksonian epilepsy and progressive loss of weight. He had become irritable, forgetful, and stupid. He died in status epilepticus within forty-eight hours and the bladder urine contained 2.5 per cent sugar. A postmortem examination showed an anemic infarct of three fourths of the spleen and the entire right kidney. The pancreas itself was hard and irregular and upon opening it was found to contain many deposits of calcium throughout the pancreatic tissue. These deposits of calcium were not calculi located within the ducts of the pancreas, but calcareous deposits throughout the gland itself. The gland tissue was largely replaced by fibrous tissue and there were scarcely any normal islands of Langerhans remaining. Dr. Wells analyzed the material, finding it was chiefly calcium carbonate and phosphate. In addition, he had tuberculosis of the lungs and an area of infarction and softening of the ascending parietal and frontal convolutions of the brain, evidently the result of an embolism or thrombosis.

Trauma of various sorts is almost of daily occurrence. Trauma is involved in the many dental extractions, and all the operations carried out in the hospitals. None are regarded by either patient or physician as likely to have any bearing upon the production of diabetes. Trauma, in order to cause diabetes, must be direct and produce serious injury to the pancreas. Conceivably, trauma might have an indirect effect, especially upon patients already susceptible to the development of diabetes by reason of inheritance. Thus, an accident

leading to a long continuing infection, such as osteomyelitis, with recurrences over a period of time, might by producing invalidism and overnutrition act as a precipitating cause. If the patient happened to have a diabetic heredity, then one might possibly hold that the diabetes resulting after such a long period of recurring infections, might have taken place a few months or a few years earlier than would otherwise have occurred. It must be remembered that even such gross lesions of the pancreas as acute pancreatitis and pancreatic carcinoma, usually do not cause diabetes because they do not involve a sufficiently large part of the pancreas.

**Psychic Trauma.**—We consider trauma of the central nervous system to include the tremendous number of injuries of the brain from flying shells and shrapnel, as well as the psychic trauma to which millions of men were subjected during the World War. Students of diabetes in Germany, France, England and in this country all agreed that there was no increase in diabetes produced by brain injuries or by the striking trauma of the World War. In the words of von Noorden, "the World War put neurogenic diabetes in its grave."

Yet, the opinion is still occasionally expressed that nervous wear and tear, emotional shock, and psychic trauma may be the cause of diabetes. Occasionally, a striking case may occur, such as the following:

Case 14,050, aged thirty-three years, gave the following history: six or eight weeks previously, because of a slight automobile accident, he had consulted a doctor who found the urine to be sugar-free. One month before the day of his examination, his weight was 210 pounds dressed, which was the highest weight he had ever had. There was no known history of diabetes in the family. His occupation was that of a labor representative, which meant that in contrast to his former activity, he was now in an executive position.

Twelve days before he was driving his own car along one of the main automobile thoroughfares leading out of Boston and had some personal friends in the car. Suddenly, a wheel came off and as he looked ahead he saw a train of large trucks approaching him so that for the moment he realized the great danger and that he might not be able to prevent his car from being run into the trucks, or else going over to the other side into the ditch. In his own words he "saw death staring him in the face." However, somewhat to his surprise he stopped the car without any accident occurring, so that there was no actual physical trauma whatever. As he walked along the street

merely of an urine test made recently, but actually blood sugar analyses and even a glucose tolerance test done within an hour of the accident!!

A teamster, thirty-two years old, described by Professor H. Gideon Wells in 1922, fell from his wagon while intoxicated, and the wheels passed over his body. At the hospital 4 fractured ribs on the left side with subcutaneous emphysema were found. In twelve days he left the hospital in apparently good condition. However, he returned in four months with the history from his family that shortly after his discharge he had developed certain mental symptoms, great thirst, pruritus, jacksonian epilepsy and progressive loss of weight. He had become irritable, forgetful, and stupid. He died in status epilepticus within forty-eight hours and the bladder urine contained 2.5 per cent sugar. A postmortem examination showed an anemic infarct of three fourths of the spleen and the entire right kidney. The pancreas itself was hard and irregular and upon opening it was found to contain many deposits of calcium throughout the pancreatic tissue. These deposits of calcium were not calculi located within the ducts of the pancreas, but calcareous deposits throughout the gland itself. The gland tissue was largely replaced by fibrous tissue and there were scarcely any normal islands of Langerhans remaining. Dr. Wells analyzed the material, finding it was chiefly calcium carbonate and phosphate. In addition, he had tuberculosis of the lungs and an area of infarction and softening of the ascending parietal and frontal convolutions of the brain, evidently the result of an embolism or thrombosis.

Trauma of various sorts is almost of daily occurrence. Trauma is involved in the many dental extractions, and all the operations carried out in the hospitals. None are regarded by either patient or physician as likely to have any bearing upon the production of diabetes. Trauma, in order to cause diabetes, must be direct and produce serious injury to the pancreas. Conceivably, trauma might have an indirect effect, especially upon patients already susceptible to the development of diabetes by reason of inheritance. Thus, an accident

however, did not seem serious enough to interfere with her housework, so she continued all that day. The next day the knee pained her severely requiring morphine for relief and the knee continued to be painful and became swollen. On December 20, she was brought into the hospital in profound diabetic coma, with plasma  $\text{CO}_2$  of 17 volumes per cent and blood sugar of 0.42 (420 mg) per cent. She required 210 units of insulin in the first ten hours in the hospital, and emerged from coma. During the next few days, however, she continued to have a slight fever for which we could not find an explanation. The knee was swollen without any break in the skin and it seemed to be due merely to an accumulation of noninfected fluid in the joint. Incidentally, under a callus on one toe of the same leg an area of infection was found, which apparently had been there for a long period of time. She continued to go down hill, became septic and a roentgenogram showed gas in the right knee joint and also extending up the thigh along the fascia. The infected areas were deeply incised for drainage but she died following a hemorrhage from a duodenal ulcer. At postmortem examination it was clear that she had a streptococcus infection of the knee joint which had broken through the joint capsule and had extended up the thigh along the fascial planes and that she died of the combination of infection and a large hemorrhage from an old duodenal ulcer.

The source of the streptococcus infection is unexplained unless the following course of events be accepted. She had a local infection in the toe of the right foot under the callus. As a result of the fall and trauma to the knee, together with the development of acidosis, the resistance to infection was diminished and the organisms escaped from the toe to lodge in the knee at the point of lowered resistance. Again, partly due to the fact that her resistance was diminished by the acidosis, the infection was able to break through the joint capsule, an uncommon event in even a diabetic, and extended up the thigh.

This case then illustrates:

1. The extreme importance of clearing up small focal infections.
2. The direct and remote dangers of trauma in diabetic patients, the always present threat of acidosis with the complications which it may bring about.
3. A latent but serious disease which, quite apart from the trauma, could have been a cause of death.

#### BIBLIOGRAPHY

2. Day Cleveland, and Ingram Arch. Neurol. and Psychiat., 33: 529, 1935.

toward a garage some distance away, hoping to get help, he noticed that his mouth was dry and he stopped at a roadside stand to get a drink of ginger ale. From that time on, polyuria and polydipsia were severe. He stated that he drank 3 or 4 gallons daily. His weight rapidly fell so that he then weighed 188 pounds dressed. His height at that time was 5 feet, 7 inches with heels. The urine contained 7.2 per cent sugar, 2+ diacetic acid, the blood sugar was 0.33 (330 mg.) per cent. In the hospital he made an extraordinarily good record with small doses of insulin, became sugar-free and one month later he weighed 203 pounds, the urine was sugar-free, and the blood sugar was 0.11 (110 mg.) per cent; he was taking 5 units of insulin morning and night.

If such cases occurred with great frequency it would be easy to be convinced of the importance of nervous shock in relation to diabetes. Actually, however, the vast majority of patients become diabetic without any such shock. In this case, it is unreasonable to disregard the man's obesity, a common cause of diabetes, in order to accept a rare and hypothetical cause. Furthermore, in those cases of glycosuria accompanying real cerebral injury, true diabetes does not result, as illustrated by the following case:

Case 8517, a girl eleven years of age, had a sudden headache at 1 o'clock in the morning and became unconscious by 3 A. M. on December 1, 1929. In a nearby hospital the urine contained a large amount of sugar and during the next thirteen hours she was given 157 units of insulin in an effort to make the urine sugar-free. The sugar in the cerebrospinal fluid was 408 mg. per 100 cc., and a second lumbar puncture yielded fluid with 417 mg. glucose per 100 cc. The only blood sugar test gave 0.08 (80 mg.) per cent after 100 units of insulin had been given. I saw her on the second day when the presence of blood in the cerebrospinal fluid suggested the diagnosis of subarachnoid hemorrhage. She made an uneventful recovery, was sugar-free, required no further insulin after the first day; but in one year again had a spontaneous subarachnoid hemorrhage at which time she was observed at the Massachusetts General Hospital. On this occasion, no sugar appeared and she was not diabetic. In November, 1936, her family physician reports that she is well and at school.

**Effect of Trauma Upon Diabetes.**—The effects of trauma upon a known diabetic patient may be difficult to interpret and yet most serious in their consequences, as illustrated by the following case:

Case 4908, aged forty-seven years at the onset of diabetes in May, 1925, fell on the stairs on December 16, 1935, with an injury to her knee. The injury

CLINIC OF DRS. R. EARLE GLENDY AND  
PAUL D. WHITE

CARDIAC CLINIC, MASSACHUSETTS GENERAL HOSPITAL

THE RECOGNITION AND TREATMENT OF CARDIAC  
NEUROSIS

IN recent years, with the increasing incidence of heart disease and the widespread publicity about it, the problem of cardiac neurosis has assumed a place of great importance in medical practice. Almost daily we are confronted with cases that must be carefully studied and treated with this condition in mind, and, not infrequently, anxious or fearful members of a family may be as difficult to manage as the patient himself.

Cardiac neurosis (or psychoneurosis) in which there is actual fear or anxiety about the heart should not be confused with the equally common condition known as neurocirculatory asthenia although quite often the two occur together, and eventually the latter may cause concern about the heart in the patient, his family, or his physician. Any neurotic or psychoneurotic state may have cardiovascular symptoms associated with it or be in part or completely based on the belief of the presence of heart disease, even with no symptoms whatever. This is very different from neurocirculatory asthenia where symptoms such as palpitation, precordial pain, dyspnea of the sighing type, faintness, dizziness, tremor, sweating, and nervousness may be present to a marked degree without any particular apprehension about the heart. There may be, and often is, a coexisting anxiety neurosis of some sort in such patients but not necessarily a cardiac neurosis, though this may develop in the course of time.

Underlying every cardiac neurosis there is, as a rule, some

and being quite apprehensive he sought an opinion and advice regarding his heart.

On physical examination he appeared perfectly well and, except for a slight elevation of the pulse rate, perhaps the result of nervousness, no abnormality was found. The blood pressure was 145 mm. mercury systolic and 90 diastolic. The heart and lungs were quite normal on fluoroscopic examination, and the electrocardiogram was normal.

*Discussion.*—Here we have an illustration of a posttraumatic neurosis, with actual belief in the presence of heart disease (cardiac psychoneurosis), attributed by the patient to his chest injury. The family history of heart disease, the sudden death of another occupant of the car in which he was riding at the time of the accident, and his own chest injury all were factors in precipitating a full-blown neurosis in an already nervous, sensitive individual. There was no evidence of actual cardiac trauma in this case; the cardiovascular symptoms did not begin until four months after the accident and when they did appear they were typically those of neurocirculatory asthenia and not of a damaged heart.

Having carefully determined the absence of significant cardiovascular disease in such a patient, and having gained his confidence, the greatest single therapeutic weapon is reassurance. Ideas which have grown and taken abnormal proportions in the mind of a patient, largely due to fear and misinformation, must be dispelled firmly but without ridicule. The method of citing examples is a useful one in demonstrating that a particular case is not unique or hopeless, and if this is tempered by judicious sympathy and an optimistic attitude toward the future, much can be accomplished in giving hope, encouragement, and a new lease on life to persons who might otherwise be almost totally incapacitated by an ailment which has no organic basis.

*Case II. Neurocirculatory Asthenia Predominating.*—An Italian laborer, aged forty-eight years, had always been well and active except for two operations in 1923, one for right inguinal hernia, the other for "ulcers of the stomach."

On May 6, 1930, while working as a hod carrier, he fell from a scaffold 15 to 20 feet to the ground and landed on his back. The right tenth and eleventh

definite exciting factor. The occurrence of heart disease, especially sudden heart death, among relatives and friends, or even simply reported in the newspapers under dramatic headlines may initiate a cardiac neurosis in one who is ready for a neurosis of some sort. The finding by a physician of a heart murmur, trivial or not, of some disturbance of rhythm which may be insignificant, of hypertension great or slight, or of actual heart disease may be the exciting spark. Undue emphasis on some detail or actual misinterpretation of x-rays or electrocardiograms may provide the stimulus in the patient's mind. Subjective sensations may be the starting point, such as a disagreeable extrasystole, a paroxysm of tachycardia, or the numerous symptoms of neurocirculatory asthenia. Likewise various pains in the chest of cardiac (angina pectoris, coronary thrombosis) and noncardiac (cardiospasm, bursitis, muscle strain, pleurisy) origin may create fear of heart disease, and, therefore in the minds of most laymen, fear of sudden death.

It will be apparent in the cases that are to follow how important it is to recognize and treat these cases early, for a long established cardiac neurosis, particularly when complicating serious heart disease, may be almost incurable.

#### CASES ILLUSTRATING THE VARIOUS FACTORS PRIMARILY RESPONSIBLE FOR CARDIAC PSYCHONEUROSES, AND THEIR MANAGEMENT

##### I. TRAUMA

**Case I. Psychoneurosis Predominating.**—A Jewish tailor, aged thirty-nine years, was seen by us on September 13, 1935. He had always been well and active, but of a nervous disposition. His father died at sixty-three of cerebral hemorrhage; his mother has heart disease.

Ten months previously, on November 27, 1934, he was in a serious automobile accident, in which the driver was killed outright. The patient had several ribs and the right clavicle fractured, and was in bed for from two to three months. x-Rays taken shortly after the accident showed a "little arthritis of the spine and shoulders." When he began to move around again he suffered considerably from backache.

Four months after the accident he began to notice dyspnea on climbing several flights of stairs, had sighing and yawning respiration at night, and felt heartache at times for no known reason. He was convinced that these symptoms were evidence of serious injury to his heart as a result of the accident.

and being quite apprehensive he sought an opinion and advice regarding his heart.

On physical examination he appeared perfectly well and, except for a slight elevation of the pulse rate, perhaps the result of nervousness, no abnormality was found. The blood pressure was 145 mm. mercury systolic and 90 diastolic. The heart and lungs were quite normal on fluoroscopic examination, and the electrocardiogram was normal.

*Discussion.*—Here we have an illustration of a posttraumatic neurosis, with actual belief in the presence of heart disease (cardiac psychoneurosis), attributed by the patient to his chest injury. The family history of heart disease, the sudden death of another occupant of the car in which he was riding at the time of the accident, and his own chest injury all were factors in precipitating a full-blown neurosis in an already nervous, sensitive individual. There was no evidence of actual cardiac trauma in this case; the cardiovascular symptoms did not begin until four months after the accident and when they did appear they were typically those of neurocirculatory asthenia and not of a damaged heart.

Having carefully determined the absence of significant cardiovascular disease in such a patient, and having gained his confidence, the greatest single therapeutic weapon is reassurance. Ideas which have grown and taken abnormal proportions in the mind of a patient, largely due to fear and misinformation, must be dispelled firmly but without ridicule. The method of citing examples is a useful one in demonstrating that a particular case is not unique or hopeless, and if this is tempered by judicious sympathy and an optimistic attitude toward the future, much can be accomplished in giving hope, encouragement, and a new lease on life to persons who might otherwise be almost totally incapacitated by an ailment which has no organic basis.

**Case II. Neurocirculatory Asthenia Predominating.**—An Italian laborer, aged forty-eight years, had always been well and active except for two operations in 1923, one for right inguinal hernia, the other for "ulcers of the stomach."

On May 9, 1930, while working as a hod carrier, he fell from a scaffold 12 to 14 feet to the ground and landed on his back. The right tenth and eleventh

ribs were fractured, the spine was said to have been injured, and there were abrasions and contusions over the back. He was in a hospital for two weeks, during which time one of the contusions on his back, near the angle of the left scapula, became infected and required incision and drainage. Following his discharge from the hospital he was unable to return to work and for a period of five and one-half months he received \$18.00 a week compensation for his disability. At the end of that time his physician pronounced him fit to resume work, and the compensation was discontinued. Thereafter he began to have palpitation and dyspnea on effort, dizzy spells, and great weakness whenever he tried to do any work. He developed pain in the left scapular region, where the abscess was opened; this pain radiated anteriorly to the apex region of the heart, and became worse on any exertion. These symptoms have continued, to a greater or less extent, over a period of five years, during which time he has not worked. Repeated examinations by competent physicians have revealed no significant organic disease.

Physical examination in September, 1935, showed a somewhat thin, but well-developed man who appeared slightly ill and dejected. There was well-marked clubbing of the fingers, evidently of the congenital type, without cyanosis; this clubbing had always been present. The color was good. The throat was inflamed, apparently accounting for a cough which was present. The teeth were dirty and carious. The heart was normal in size, shape, rhythm, and sounds, no murmurs being present. The pulse was regular at a rate of 60; the artery walls were soft. The blood pressure measured 120 mm. mercury systolic and 80 diastolic. The lungs were clear and the abdomen normal except for the laparotomy and herniotomy scars. The reflexes were normal. The exercise test (going up and down a flight of stairs three times) was normal, the pulse rate rising to 112 and returning to 80 within one minute. Fluoroscopic examination, 7-foot chest plate, and electrocardiogram were normal.

*Discussion.*—This case, in contrast to Case I in which there is actual belief in the presence of heart disease, represents the frequent posttraumatic state, in which symptoms of *neurocirculatory asthenia* are outstanding; they may continue for years in some individuals, particularly in those who are naturally inclined to nervousness and vasomotor instability. Too much rest, without sufficient diversion and reassurance at the beginning, is likely to prolong the symptoms, as in this case, thus diminishing the possibility of successful therapy as time goes on. Disability benefits received over long periods of time, particularly when they exceed the usual wages, though doubtless due the patient in whole or in part, do not act to hasten recovery and often result in litigation for further compensation which in turn acts as an aggravating factor to the production of symptoms in persons with neurocirculatory as-

thenia. On the other hand, there are a few victims of accidents who become malingerers as a means of satisfying their "covetous wishes," but almost without exception they can readily be detected by obvious discrepancies between the history and the symptoms and signs. No malingerer should continue so for long in the hands of scrupulous physicians.

The management of neurocirculatory asthenia of long standing is difficult. It requires tact and perseverance in running down hidden factors which may be prolonging the symptoms. Where it is obvious that any physical impairment exists this should be corrected if, in the physician's opinion, no psychic harm will result. Even though a patient is greatly incapacitated by his symptoms he should be encouraged to engage in some gainful occupation, no matter how small, and in pleasant diversions, social or otherwise. Not infrequently patients with neurocirculatory asthenia are free of symptoms when under the stress of their daily work or in an amiable social gathering, their symptoms returning when alone or in an unpleasant social or domestic environment. Graduated exercises, improved hygiene, exemplary habits as to the use of tobacco and alcohol, and special attention to regularity in eating and resting should be emphasized as important factors in the management of neurocirculatory asthenia. Medicinal or sedative therapy is rarely necessary.

## II. NEUROCIRCULATORY ASTHENIA

Case III Neurocirculatory Asthenia Precipitated by Postoperative Hemorrhage and Nervous Shock Leading to a Cardiac Neurosis and a Severe Psychosis.—An unmarried Jewess, aged twenty-eight years, was seen by us on October 5, 1936. As a child she was tense and nervous, as was her mother, but she went through high school and two years of private school successfully. At the age of fourteen she had a tonsillectomy which she greatly feared. A postoperative hemorrhage after her return home necessitated a quick trip back to the hospital by ambulance. She was badly frightened by this episode and her heart beat rapidly and uncomfortably for a while. This subsided after the difficult time with her tonsils, but recurred five years later prior to an appendix operation.

At the age of twenty she had the shocking experience of having her fiancé die at the time of pneumonia. Following this the tachycardia and palpitation returned and persisted more or less. For several years she tried to lose herself

in exciting distractions but finally collapsed with "nervous prostration" and the certainty in her own mind that she had heart disease and did not have long to live. Subsequently she remained in bed for months and went through a typical schizophrenic episode with hallucinations and delusions mostly centering around death from heart disease.

In July, 1934, she was admitted to a private sanatorium, at that time in a convalescent state from schizophrenia. Improvement has been steady during the past two years but she still fears heart disease and continues to have such symptoms as dyspnea on stairs, sighing respiration, heartache frequently, occasionally momentary sharp stabs of pain over the heart, palpitation, giddiness, easy fatigue, tremor, and increased sweating, altogether typical of neurocirculatory asthenia. Although she admittedly would like to resume the responsibilities of her former environment she doubts her ability to do so on account of her heart, and returns to a frank interest in her heart function whenever such a possibility is mentioned.

She had been given digitalis early in her illness but its effect was unknown. Otherwise her treatment had consisted of rest, sedatives when necessary for sleep, and psychotherapy.

On physical examination she was alert and sighing occasionally. The heart was normal in size, sounds, and rhythm. There were no murmurs. There was no evidence of congestive failure. The pulse rate varied at the apex and wrist from 80 to 100. She was a little nervous at the time. The blood pressure measured 115 to 120 mm. mercury systolic and 70 diastolic. Fluoroscopic examination showed a small vertical heart. The electrocardiogram showed normal rhythm, rate 100, with a tendency to slight right axis deviation (normal for her build), and a normal chest lead.

*Discussion.*—A case of this kind offers a real problem in management. Not only are there a fear and a delusion of heart disease, but the many symptoms of neurocirculatory asthenia keep this fear alive, because they are interpreted by the patient as indicative of heart disease. It is necessary to offer a full explanation of neurocirculatory asthenia, so far as we understand it ourselves, at the same time reassuring the patient of its relative unimportance. Careful, sympathetic reeducation should be carried out as normal physical and social activities are resumed. Occasionally sedative or tonic medications may be used with good effect.

### III. ARRHYTHMIAS

**Case IV. Premature Beats.**—A traveling salesman, aged forty-five years, was first seen by us June 30, 1928, when he complained of discomfort in his chest consisting of heartache and brief stabs of precordial pain lasting a second at a time, occurring off and on through the day, but most noticed at

night when in bed. He had been working hard for many years without vacations and was nervously exhausted.

He had no other symptoms except that he occasionally observed at the moment of a stab of pain that the heart beat irregularly.

Physical examination at this time showed no abnormalities whatsoever except for occasional premature beats. The electrocardiogram was entirely normal, but the next month, in July, it showed auricular premature beats.

This patient was reassured, but felt quite certain that we were concealing from him the diagnosis of coronary disease with angina pectoris. He returned a half a dozen times within a few months, certain that he must have some serious heart disease. No evidence of heart disease was ever found. Gradually the intervals between visits increased until finally in September, 1932, four years later, he appeared still showing premature beats, but with a smile and a confession that he no longer thought we were concealing the truth from him, and that he probably did not have angina pectoris. Now in 1936, he is well, working actively, and undisturbed by his premature beats.

*Discussion.*—This man illustrates a condition, very commonly found, of distress and worry over the occurrence of extrasystoles, which may at times be so disagreeable in a sensitive person as to cause severe pain which may be confused with angina pectoris in careless history taking. It is obvious that very careful examination and reassurance at the start are the most important features. Reassurance may need to be continued in large frequent doses, as in the patient just discussed, but finally it proves effective. Later, heart disease may actually follow the finding of extrasystoles, but this seems, in the few instances in which one finds it, rather a coincidence. Although it is possible that in very rare cases heart disease, for example of the coronary type, may be ushered in with extrasystoles, we have no certain knowledge thereof. If the extrasystoles are very uncomfortable, one may use triple bromides,  $7\frac{1}{2}$  to 15 grains, three or four times a day for a few days or a week or two at a time, or quinidine sulphate 3 grains three or four times a day for a few weeks, or both these medicines together. The bromide acts chiefly to dull the perception of the extrasystoles while the quinidine tends to prevent them. Digitalis is generally contraindicated. It can itself produce extrasystoles. Finally, the advice that Mackenzie gave concerning the extrasystoles is also to be remembered, that after all factors such as excessive tobacco, fatigue, and

indigestion have been ruled out or controlled, exercise in the open air may be the best remedy of all.

**Case V. Paroxysmal Tachycardia.**—A twenty-eight-year-old accountant was seen by us in May, 1936. He had had pneumonia at the age of fifteen. Otherwise his general health had been good. At the age of thirteen years, while playing tennis, he had a sudden attack of rapid regular heart action, without pain or dyspnea, lasting a half hour. From that time until two years ago he was badly crippled by paroxysms of regular tachycardia lasting for hours at a time and recurring every few days on the slightest provocation such as the excitement of meeting a friend, carrying on business, or mild exercise. He suffered no pain but his attacks were attended by forceful rapid palpitation and such great apprehension of the consequences that he was, in fact, an invalid, unable to indulge in normal activity without fear of inducing a spell. He tried various medicines without benefit, but did not use quinidine or digitalis. No measures such as carotid sinus pressure or ocular pressure were used. In the year 1933 a tonsillectomy was advised and attempted, but the adrenalin, which was used in combination with the local anesthetic (novocain), initiated such a severe attack of palpitation that the procedure was abandoned. One year later his tonsils were successfully removed and he had slowly improved ever since. His attacks had become now less frequent and were of shorter duration. The last one had occurred one month prior to examination and was of two hours' duration.

On physical examination there were no abnormalities except for his slight build. He was obviously of a nervous and sensitive disposition. Fluoroscopic examination showed a normal-sized, vertical heart. The electrocardiogram showed sinoauricular tachycardia, rate 120, moderate right axis deviation consistent with his build, upright T waves in Lead I, normal P waves, and a normal chest lead.

In treatment this young man was taken out on the tennis courts and induced to play again, a thing he had feared and avoided for years. At first he was alarmed and bothered by the normal sinoauricular tachycardia that quickly ensued, but after brief rests and much reassurance he continued the game and finally was able to play without apprehension or symptoms.

**Discussion.**—This history is plainly that of a normal, irritable heart with paroxysms of tachycardia, undoubtedly paroxysmal auricular tachycardia, inducing great nervousness and apprehension which in turn, by their persistence, served to perpetuate a semi-invalidism. Just what part the tonsillectomy played in diminishing the frequency of attacks is problematical. At any rate the psychological effect was a good one. Of most importance, however, were reassurance and observation during the playing of tennis, at which time it was obvious that the

tachycardia that had troubled him most of the time had been sinoauricular and not paroxysmal, although originally true paroxysmal tachycardia had been to blame. With a regimen of increasing exercise this young man has rapidly improved.

#### IV. ORGANIC HEART DISEASE

The types of organic heart disease most commonly associated with a cardiac neurosis are the rheumatic, the hypertensive, and the coronary. Cardiovascular syphilis is in our experience rarely accompanied by a cardiac neurosis. Congenital heart disease and the cor pulmonale are in themselves rare and therefore present very infrequently a combination with cardiac neurosis.

**Case VI. Rheumatic Valvular Heart Disease (Mitral Stenosis and Aortic Regurgitation, Both Slight, and Neurocirculatory Asthenia).**—A single teacher, aged twenty-eight years, was seen by us on August 19, 1932. Her parents had died when she was quite young. She had always been sensitive and of a nervous disposition like other members of her family. Her tonsils were removed at the age of eight years. At the age of twelve years she was laid up for three months with an illness which she recalls as pneumonia, but which left a "leaking valve" in her heart. She had never been in robust health since that time. Following her original illness she had recurrence almost yearly for several years presumably of active rheumatic infection, but there had been no serious sickness for about ten years. Her immediate symptoms, which had been present for many years, consisted of insomnia, heart consciousness in the form of tachycardia and forceful palpitation, mostly at night, heartache, dyspnea of the sighing type, and nervousness. The slightest things worried her and she tired easily. Her symptoms were always worse in the early morning after a sleepless night. She was much concerned about the state of her heart.

On physical examination she appeared quite well but nervous. There were no abnormalities except for slight cardiac enlargement, a moderately loud apical systolic murmur, a slight middiastolic rumbling murmur at the apex, and a slight early blowing diastolic murmur along the left sternal border. The pulse rate was 72, the blood pressure measured 125 mm. mercury systolic and 70 diastolic. There was no evidence of congestive heart failure. Fluoroscopic examination showed a full-sized heart; the cardiothoracic ratio was just within normal limits. The electrocardiogram was normal.

When seen last by us, in April, 1936, she was still nervous and tired easily. Palpitation and heartache were prominent symptoms when she was very tired. On account of fear of overdoing she had given up regular teaching and was working irregularly as a substitute. But in spite of her fear and apprehension about the heart there had been no essential change in heart size or function over a period of four years.

*Discussion.*—This young woman is one of a large series of cases with a slight amount of rheumatic valvular disease in whom either the fear of the heart disease or the symptoms of neurocirculatory asthenia or both have created a cardiac neurosis. It is of vital importance in the proper handling of these cases to make it clear to the patient at the outset that there is not enough heart disease to produce symptoms or early disability or death. The neurocirculatory asthenia must be recognized, however, and treated intelligently by reasonable limitation of activity and strain as well as by reassurance.

**Case VII. Hypertension.**—A woman, aged sixty-nine years, was first examined by us in June, 1936. She had had severe diphtheria as a child, asthma provoked by a variety of factors off and on for thirty-five years, and severe grippe seven months previously. Hypertension of variable degree up to 250 mm. mercury systolic was known to have been present for four or five years. She was of a nervous, sensitive disposition and, in addition to her natural concern over her blood pressure, had been alarmed by physicians who had found such high blood pressure.

In 1932 she began to have some substernal oppression and palpitation on effort and excitement, and also at night, following attacks of asthma for the last two years, but she was not worried by this symptom. She had been slightly dyspneic all her life and this had been moderately increased during the past two years especially in the form of asthmatic breathing during an attack, on effort, or at night, at which time there was some orthopnea. All of her symptoms were worse following the severe grippe of the previous winter but were improving. She was very nervous, slept poorly, and was fatigued easily. In spite of this she insisted on taking 2 cups of strong coffee in the evening.

Her treatment had consisted of the use of belladonna, hyoscyamus, and bromide during the preceding year and of codeine and aspirin occasionally. Ephedrine and adrenalin had disagreed with her.

Physical examination showed very little out of the way. She was evidently nervous as had always been the case during her entire lifetime. The heart was slightly enlarged and there was a slight systolic murmur at the base. The pulse rate was a little high, measuring 96 at apex and wrist, largely the result of nervousness and the overuse of coffee. After a pleasant reminiscence of former days when patient and examiner had been neighbors on a lake shore during summer vacations, the blood pressure measured only 170 to 175 systolic and 95 diastolic. There was no evidence of congestive failure. The electrocardiogram was normal except for an increased heart rate.

*Discussion.*—Although this patient is well advanced in years and undoubtedly the victim of a moderate degree of

hypertension and coronary disease, she has been unduly alarmed as to the seriousness of her condition. With reassurance as to the future, advice to avoid nervous strain and excessive fatigue, a small amount of sedative medicine, the omission of coffee in the evening, and a quiet summer at the seashore, she reported great improvement at the end of two and one-half months. At that time the pulse was regular at a rate of 84, the blood pressure was 170 to 165 systolic and 90 diastolic, and her mental and physical improvement was obvious. She was further reassured, advised to continue along the same lines, and to have her blood pressure measured only every six months or less often.

**Case VIII. Coronary Thrombosis.**—A forty-nine-year-old physician was first seen by us in March, 1934. He had had lobar pneumonia at the age of twenty-one and had suffered from migrainous headaches for many years. His habits were exemplary except for the excessive use of tobacco. On account of easy fatigue and exhaustion he had consulted his local physician eighteen months previously but the only physical abnormality detected was a dead tooth which was later removed. A year afterward, on October 17, 1933, while sitting quietly, he noticed for the first time mild substernal discomfort lasting a few minutes. An hour later, while practicing golf shots, he was taken acutely ill with severe, tearing substernal pain radiating into the arms. The pain lasted for thirty-six hours in spite of  $\frac{1}{2}$  grain of morphine sulphate subcutaneously and several doses of pantopon. Fever was recorded up to  $101^{\circ}$  F. daily for a week, and the white blood count was much elevated, up to 25,000, during that time. A pericardial friction rub was heard on the third day of his illness and lasted for ten days. There were recurrences of the pain for a few weeks, but when seen in March there had been no pain for more than two months. His blood pressure had been low (90 systolic) for weeks, but was now normal. The electrocardiogram three days after the attack was typical of coronary thrombosis. He remained in bed for three and one-half months, hardly moving at all during the first five weeks of that period. The only medicines he received were narcotics and later theominal. He now felt fairly well and was sitting up two to three hours a day.

On physical examination he appeared slightly ill and his skin was sallow. Aside from slight cardiac enlargement no other significant abnormalities were present. The pulse rate was 68 and the blood pressure measured 125 mm. systolic and 80 diastolic. He was reassured and advised gradually to resume his practice and normal activity, which he did.

When seen by us again on August 6, 1935, he reported that he had been in excellent state of health and able to do light practice until the sudden death of a patient from coronary thrombosis in March, 1935. A few days after this he felt a mild chest pain—not severe—lasting a few hours. Fearing

another attack of coronary thrombosis he went to bed for six weeks but did not call a doctor. He had not returned to practice, and had led a quiet restful life. There was slight high substernal discomfort at times, but not on effort such as playing 9 holes of golf. He continued to smoke 20 cigarettes daily. On physical examination he now appeared well and the slight cardiac enlargement noted previously was the only abnormal finding. The electrocardiogram showed normal rhythm, rate 90, slight right axis deviation, low T waves in Lead I and upright T waves in Leads II and III.

With the reasonable assumption that his myocardial infarct had long been well healed and that most or all of his symptoms were the result of fear and anticipation of further trouble he was once more reassured and advised to omit tobacco and to return to work. When last heard from in November, 1935, he was in good condition and returning to the practice of medicine.

*Discussion.*—This case is an example of many others of cardiac neurosis following coronary thrombosis. It has been our experience that it is often more difficult to treat the nervous prostration in these cases than the coronary thrombosis itself, especially in physicians. The lesson is obvious, that a clear presentation of the whole situation should be made *early* in the illness to the patient, with ample reassurance, if justified, in order to prevent such a cardiac neurosis as developed in this case.

**Case IX. Coronary Disease Discovered by Electrocardiogram (Symptoms Due to Neurocirculatory Asthenia).**—A dentist, aged thirty-four years was seen by us in September, 1936. He had always been well and active, and a hard worker with no vacations. For four years he had been under much strain because of his mother's serious illness from hemiplegia, and had lost much sleep in caring for her at night. Six months previously, when very tired, he began to be troubled by aching pain, sometimes sharp, rather high in the left anterior chest, lasting a day or two at a time and not related to any effort or to meals. This had recurred frequently but had not been present during the preceding two weeks. Palpitation, slight dyspnea, dizziness, and faintness had occasionally been present with the chest pain, and he sighed frequently. He felt best while playing golf. Having access to medical literature he had read the books and was much worried by the ache in his chest, fearing heart disease. He had had no treatment except aminophyllin and sedatives without benefit. He was told that his electrocardiogram was abnormal.

Physical examination was entirely normal except for slightly enlarged tonsils. He was nervous and apprehensive of his cardiac condition. The heart was normal in size, sounds, rate, and rhythm. There were no murmurs. There was no evidence of congestive failure. The pulse rate at apex and wrist was 84. The blood pressure measured 115 mm. mercury systolic and 70 diastolic. The Wassermann reaction was negative. Fluoroscopic examination revealed no

abnormality. The electrocardiogram showed inverted T waves in Lead I, low voltage of the QRS waves in Leads II and III, and rather low voltage of the QRS waves in Lead I. In Lead IV the QRS waves were normal, but the T waves were upright.

This electrocardiogram is certainly indicative of a poor coronary blood supply in the region of the apex of the left ventricle, doubtless due to atherosclerosis and narrowing of the anterior branch of the left coronary artery, but it is difficult to say with any degree of certainty that serious clinical trouble is in the offing. Neurocirculatory asthenia and cardiac neurosis induced by fatigue and nervous strain were certainly responsible, in large part, for his symptoms, and although his future may be regarded as uncertain it may actually be fairly good.

*Discussion.*—This case illustrates forcibly the difficulty in treating a person whose symptoms are not those of heart disease but who nevertheless has important heart disease. It also shows the importance of the electrocardiogram in detecting coronary artery disease, the serious consequences of which may be forestalled or diminished through the avoidance of physical and mental strain and a quiet, sane manner of living.

#### V. MISINTERPRETATION OF SYMPTOMS AND SIGNS

**CASE X. Noncardiac Cause of Chest Pain (Muscle Strain).**—A physician, aged forty-eight years, was first examined by us on August 28, 1933. Except for a gangrenous appendix in 1918 he had always been well and active. For a number of years there had been a tendency to blanching and coldness of the fingers on slight chilling.

On August 19, 1933, feeling quite tired from his busy practice, he started on a vacation and became quite active physically playing golf and tennis and on one day he picked oysters. A few days later, on August 26, 1933, while dusting the roof of his car he suddenly felt a severe soreness in the anterior left axilla sufficient to cause him to stop what he was doing. For two days the soreness continued in dull form, but steadily decreasing, and movements of the left shoulder and deep inspiration made it worse. There had been some sighing respiration but no true dyspnea and no substernal or back pain. That same day (August 26) he had much gas and diarrhea and the latter continued slightly for two days. With the possibility of angina pectoris in mind he had taken nitroglycerin three times with no noticeable effect. He was much worried by the chest pain and feared heart disease.

Physical examination, fluoroscopy, and electrocardiogram revealed no significant abnormalities. He was reassured by this fact and advised to lead a normal but less strenuous life. His symptoms disappeared promptly and with the exception of influenza with intestinal symptoms the following winter he has been well.

*Discussion.*—In this case there is little doubt that the underlying factors in the production of his symptoms were fatigue, slight muscle strain in the pectoralis group of muscles, and perhaps distress from excessive amounts of gas in the bowel. Likewise, symptoms of such noncardiac conditions as bursitis, pleuritis, and cardiospasm may be interpreted by the patient as evidence of heart disease.

Of the greatest importance in the management of such cases, aside from the actual treatment of whatever noncardiac condition exists, is to be sure that there is no coexistent heart disease. This is not always easy, for even severe coronary disease may be present at times with only slight or suggestive clinical or electrocardiographic findings. When reasonably sure that symptoms are not the result of cardiac causes the patient should be urged to be normally active as soon as his condition warrants it.

**Case XI. Heart Murmurs, Especially the Functional Pulmonary Systolic Murmur.**—A little girl, aged four and one-half years, was examined by us in February, 1934. She was a small baby, weighing only 4 pounds at birth but otherwise normal. She was subject to frequent colds. Her tonsils had been removed in July, 1933, because they were enlarged. She had recently had chickenpox.

At the beginning of the school year in September, 1934, she was examined with the rest of the children and her mother was told that there was some abnormality of the heart. It was impossible to elicit any story of cardiac symptoms from the mother or the child herself. Nevertheless there was great concern on the part of the parents who felt that the child had a poor appetite and became tired too easily, and they were beginning to interpret every complaint the child offered as evidence of heart disease.

Physical examination revealed a very slight functional pulmonary systolic murmur, dispelled on full inspiration. There was no cardiac enlargement either by physical examination or fluoroscopy. The heart sounds were good, the rhythm was normal. The electrocardiogram was normal.

*Discussion.*—This case affords an excellent example of parental solicitude and alarm which, if allowed to continue without proper reassurance, may result in the development of cardiac neurosis, not only in the child as she grows older, but in the entire family. A slight pulmonary systolic murmur, such as was present in this case, is the commonest of all heart

murmurs and may be considered as being entirely within normal limits. The failure to recognize it as such may do immeasurable harm. Similarly, undue emphasis may be placed on murmurs due to organic changes, when in the absence of cardiac enlargement or disability, they may be, in fact, of little more importance than the harmless functional pulmonary murmur.

**Case XII. Unimportant Electrocardiographic Variations or Artefacts.**

—A young man, aged thirty-two years, was first seen by us on October 23, 1936. Except for hay fever he had always been well and active, but overweight. In recent years he had been overworking and smoking heavily. He had reduced his tobacco to 3 or 4 cigarettes daily. His father has angina pectoris.

In June, 1936, four months previously, he first began to be bothered by a little dyspnea in the form of air hunger with sighing respiration, occurring at any time, but mostly when very tired from overwork. One month later while in a barber's chair having a haircut he was seized by a sense of suffocation and after the haircut he had to rush outdoors for air. He then consulted a doctor who found him breathing deeply and rapidly. He was put to bed where he remained for four weeks with much sighing respiration at first and then gradual recovery. He was seen in consultation by a local specialist who made a diagnosis of "soldier's heart" after obtaining a normal electrocardiogram. But because of the persistence of some sighing he went to a distant clinic for study in September, 1936. An electrocardiogram taken there was said not to be wholly normal and he returned home with the impression that he was a probable "heart case." Since then he had been in a state of nervous apprehension, the sighing respiration had continued, and a new symptom consisting of a little headache had been present for about four weeks.

Except for apparent nervousness and obesity physical examination was quite normal. The heart was normal in size, shape, and sounds. There were no murmurs. The pulse was regular at a rate of 84. The blood pressure measured 140 mm. mercury systolic and 85 diastolic. A subsequent electrocardiogram was normal.

*Discussion.*—Here we have an example of a case of marked cardiac neurosis set off by a fear both by himself and by others that his sighing meant heart disease. Unfortunately, while he was convalescing from this state of mind and body his apprehension was stimulated again by overemphasis of some trivial variation of his electrocardiograms from the usual average normal. There was no evidence of real heart disease in his case.

Unimportant electrocardiographic variations that are most commonly misinterpreted as evidence of heart disease are slight grades of left and right axis deviation, inverted T waves in Lead III (and particularly total inversion of Lead III), very slight elevation or depression of the S-T segment in Leads II, III, or IV, slight slurring of the QRS complexes without widening, and P-R intervals of 0.19 to 0.20 second in duration. The commonest artefact, aside from those obviously due to motion of the patient, is a reversal of leads in applying the electrodes.

**Case XIII. Unimportant x-Ray Variations.**—A young engineer, aged thirty years, was first seen by us in November, 1922. He had had repeated attacks of rheumatism since the age of twelve, and valvular heart disease was known to have been present since the age of eighteen. Lately there had been a few orthopneic attacks and some dyspnea and palpitation on moderate exertion. Otherwise he was in good health. On physical examination he appeared well. There was a soft, blowing diastolic murmur along the left border of the sternum, and a slight middiastolic murmur at the apex, recumbent and after exertion. The pulse rate was 80. The blood pressure measured 140 mm. mercury systolic and 65 diastolic. There was no evidence of congestive failure. He was reassured and advised to lead a normal life.

Seven years later, in October, 1929, he was seen again. His complaints at that time were continuation of the dyspnea on exertion which had been present for many years, a little heartache now and then, especially when tired or on lying down at night, rapid pulse, and slight palpitation. He was much worried by his symptoms. He had been taking digitalis for a few days. Examination at that time was much as before except that he was overweight and the middiastolic murmur at the apex was less definite. The blood pressure measured 140 mm. systolic and 80 diastolic. Electrocardiogram showed sinoauricular tachycardia, rate 120, well-marked left axis deviation, inverted T waves in Lead I and flat T waves in Lead II. He was advised to omit digitalis and to lose weight, and was further reassured about his heart.

His third visit was six years later in January, 1936. He reported a fair state of health except for slight recurrences of rheumatism in 1933 and 1934, much nervousness and insomnia due in part to obligatory work at night in the past three years, and increasing dyspnea and fatigue during the past few weeks. He had again taken digitalis for a few days. He brought with him x-rays of his chest which had been interpreted as showing great cardiac enlargement. This had caused him and his family much concern. Again his findings were as before. There was a slight degree of cardiac enlargement, the slight aortic murmur was still present, but no mitral diastolic murmur could be heard. It was evident on fluoroscopic examination that the increased cardiac measurement on the films had resulted from adding the area of dulness outside the heart shadow, caused by epipericardial fat, to the transverse diameter of the heart. He was again reassured and advised to stop night work.

*Discussion.*—Many x-ray films of the shadow of the heart and great vessels are misinterpreted. Usually the error lies in including in the transverse diameter or cardiac area measurements the shadow of the epipericardial fat so often present, thus increasing the apparent size of the heart sometimes to a considerable extent, or in interpreting as aneurysm tortuosity of the aorta, mediastinal or lung tumor, or simple dilatation of the pulmonary artery. Such misinterpretation may result in a serious cardiac neurosis. It should be carefully excluded or quickly corrected if already made, with full reassurance of the patient.

#### SUMMARY

We have herewith presented 13 cases illustrative of the diagnosis and treatment of cardiac neurosis excited by the more common factors, namely, trauma, neurocirculatory asthenia, various arrhythmias of the heart, the knowledge of organic heart disease (rheumatic valvular disease, hypertensive heart disease, and coronary disease as examples), and the misinterpretation of symptoms, heart murmurs, electrocardiograms, and x-ray films.

## CLINIC OF DR. WILLIAM H. ROBEY

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND  
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY  
HOSPITAL, THE DEPARTMENT OF MEDICINE, HARVARD  
MEDICAL SCHOOL

---

### THE RECOGNITION AND TREATMENT OF PAROXYSMAL RAPID HEART ACTION

THERE are three conditions of heart action which attract the patient's attention more readily than any others, premature contractions, tachycardia and palpitation. Angina pectoris when not intense is often borne much longer because the frequently accompanying indigestion is regarded as a cause of either pain or oppression beneath the sternum. Most of the early symptoms of organic heart disease in the cardiac area are tolerated by the patient so long as rate and rhythm are not noticeably disturbed, but when they are, he hurries to the physician to learn their meaning and the physician must decide between a functional and an organic disorder. This decision is not always easy; sometimes it is very difficult.

*Simple or sino-auricular tachycardia* is a term used to indicate merely the increased rate caused by normal overactivity. The average cardiac rate in a man is 72 per minute, in a woman 76, and in a child 90. Some normal individuals who persistently have a slightly higher or lower rate without other changes, regard the rate as normal and we are unable to disagree with them. Most people recognize a normally increased rate and do not inquire about it; they know that if they hurry or are agitated the heart will increase in rate but it returns to normal as soon as the emergency is over. Often we test hearts by one of the many exercises which have been devised,

the stair-climbing test which is convenient, inexpensive and as efficient as any. The cardiac rate is taken while at rest and then the patient ascends 20 ordinary steps at a lively pace. Immediately the pulse is counted and is considered within normal bounds if the rate increases 20 beats and returns to its original count within five minutes. Many healthy hearts accelerate much less than 20 beats and will return to the original rate in a minute or two. Diseased hearts will often not exceed the normal heart in rate after this test but the return to the original count is slower. Naturally the physician selects the patients for this test with caution, and a considerable number exhibit sufficient signs of cardiac or circulatory disease or small endurance beforehand to make the test unwise or unnecessary. Sino-auricular tachycardia must be differentiated from auricular paroxysmal tachycardia because prognosis and treatment are quite different. If tachycardia has a gradual onset and offset it is probably due to loss of vagal control and is therefore due to some recognized cause outside the heart. We inquire carefully into the history of infectious diseases which may have been a cause of heart involvement and we examine the heart for evidences of disease, for undue or idiosyncratic reactions to tobacco, tea, coffee, and less frequently alcohol; into drugs like atropine which paralyzes the vagus, or adrenalin which stimulates the sympathetic nerves. I have just seen a young man of twenty-seven in whom no disease of the heart or any other organ could be discovered except a benign infection of the prostate which has existed for the last two months. His tachycardia has occurred, however, at long intervals during the last three years. Previous attacks may have been induced by overindulgence in tobacco and the more recent ones possibly by his infection. He has never had rheumatic fever. The urologist who sent him to me is trying to cure his prostatitis and I have cut down his tobacco. An electrocardiogram taken during an attack showed an auricular origin, normal sinus rhythm with a rate for auricles and ventricles of 100, a P-R interval of 0.20 second and a QRS of 0.06 second, with no axis deviation nor other abnormalities. A second electro-

cardiogram taken a week later did not differ from the first test except that it showed the rate for auricles and ventricles to be 75. About this time he was married and being anxious to have life insurance he attempted to take out a policy but frankly told the medical examiner about his occasional attacks of rapid heart action with the result that the insurance company has for the time being declined him. It is very important for us to prove that he has simple harmless tachycardia since no evidence of organic cardiac disease can be discovered.

Whether we are dealing with simple tachycardia or paroxysmal tachycardia the etiology is much more difficult in the young adult than in the middle-aged or elderly because in the young signs of heart disease are often absent.

Sino-auricular tachycardia is a regular rapid heart with gradual onset and offset generally due to the release of control of the sino-auricular node by vagus depression and sympathetic nerve stimulation.

The difference between simple and paroxysmal tachycardia is sometimes largely a matter of history. Lewis states that while the patient describes the abrupt onset, a statement of gradual ending must be received cautiously since in some patients long paroxysms end in a series of quite short ones or in a declining number of extrasystolic interruptions. Paroxysmal tachycardia usually is unexpected, whereas simple tachycardia often comes at definite times or is induced by some recognized act or some indiscretion. For example, I have a patient who is a healthy middle-aged man but for years the smoking of 2 or 3 additional cigars during an evening card game will bring on a simple tachycardia. The old rule is that the pulse rises about 10 beats in rate for every degree of fever. While most febrile diseases cause this rise, typhoid fever is an exception, the pulse being little elevated above the normal during the active phase of the fever but with convalescence it may rise as soon as the patient is allowed to sit up; putting the patient back to bed for two or three days will generally restore the heart to its normal rate. The increase is probably due not to the immediate effect of toxins but to the exhausting effect of

a long febrile disease on a heart which is then asked to do more than has been its habit during the course of the disease. Particularly diphtheria and poliomyelitis may paralyze the vagus nerve and abolish its control of the heart.

Infectious diseases rarely damage the structures of the heart, though occasionally pneumonia leaves an endocarditis. The great exception is rheumatic fever which need not be discussed at this time. If the victim of an acute infectious disease escapes the effect of its general toxemia, his heart likewise escapes. Even when the heart is made to beat rapidly during the course of an acute disease, the duration is short and if the heart was healthy at the onset of the infection, the comparatively brief acceleration is usually harmless. In 1918 some persons convalescent from attacks of so-called "influenza" died suddenly and it was said that their hearts had been damaged by the acute infection, but as a matter of fact these people in many instances were suffering from some previously unrecognized cardiac pathology before the inception of the acute disease.

*Hyperthyroidism* is a cause of simple tachycardia and palpitation. Few additional symptoms may be present but the basal metabolic rate is the key to the cause. This condition must be stopped because while not immediately harmful, a long continued thyrotoxicosis with its constantly rapid cardiac rate may lead to exhaustion of the heart muscle.

*Menopause* is also another cause and it is not unusual to have women during this phase present themselves because they are convinced that they have heart disease. Inquiry into their history and a careful physical examination will eliminate other possibilities after which the use of one of the ovarian extracts will frequently clear away this distressing symptom. A recent case is sufficient to illustrate this cause of simple tachycardia. An unmarried school teacher, fifty-two years old, complained of palpitation, pain in the heart area and at times a rapid action. There was no history suggesting cardiac inefficiency nor anything in the physical examination and laboratory tests which pointed toward heart disease. The symptoms

of pain and tachycardia were coincident with irregularity in menstruation and the use of corpus luteum extract, 5 grains three or four times daily, has entirely relieved her cardiac symptoms. Naturally this cause is arrived at by thorough elimination.

**Neurocirculatory asthenia**, so much studied during the World War but seen also in private practice, occurs in certain individuals who when subjected to new and agitating conditions develop a train of circulatory manifestations of which sino-auricular tachycardia is a striking sign.

A Jewish youth of twenty years with an excellent family history was seen because of rapid heart action, palpitation and cardiac pain which his family physician had diagnosed as "heart strain." As a small child he had scarlet fever and has had occasionally a sore throat without constitutional disturbances. He has never had any disease suggesting rheumatic fever. His appetite has not been so good during the last five weeks but his digestion and bowels have been normal. He takes a general diet, eats slowly, and does not use alcohol nor tobacco. Until the present illness he has considered himself in perfect health. Three years ago, after graduation from a high school, he secured a shipping position in a shoe factory and continued there very contentedly until the factory closed last summer. For a brief period he worked in a cleansing shop but the duties were almost too easy and after a short time he looked about for another job in the shoe business. He secured one but at the end of the fifth week he felt ill and saw his family physician who said that he had a weak heart. After three weeks in the wholesale shoe house he began to have rapid action (varying in rate, he explained), pain in the cardiac area, palpitation and occasionally nocturnal breathlessness. He described his work in some detail, working two or three times as the story progressed. He began work at 9 A. M., had one hour for lunch and then returned until 6 P. M. Three evenings a week he worked from 7 until 11. All this time he packed boxes with shoes and placed the boxes on shelves, or he sorted sample shoes, brought in by the traveling salesman, kneeling on the floor throughout the day. A boss shipper moved about among the groups of assistant shippers constantly urging them to work faster. He was a well-developed and well-nourished young man with normal teeth and throat and good color. There were no glands. The cardiac area by fluoroscope showed the great vessels to be 4.2 cm., the right border 4.5 cm. from mid-sternum and the left border 6.8 cm. There were no abnormalities in the shape of the heart. The impulse was not heaving. No murmurs could be detected in any position, even after exercise. The rate varied between 84 and 120 and usually began to rise with examination of the heart. Clearly the rhythm suggested sinus arrhythmia. The blood pressure was 110/70. The electrocardiogram showed a rate of 120 for auricles and ventricles. The P-R interval was 0.18 second and the QRS complex was distinct. The T wave was upright in all leads and there was no axis deviation.

deviation. The lungs, abdomen and urine were normal. The patella reflexes were hyperactive but there was no trembling nor did the electrocardiogram show somatic tremor.

The emotional state during the recital of the medical history, the tachycardia with varying rates, the cardiac pain, which is not uncommon in nervous persons with tachycardia and palpitation, and the exaggerated reflexes all suggested a sino-auricular tachycardia and an emotional state. It was quite similar to cases of mild neurocirculatory asthenia seen during the World War. I believe that when this young man secures a congenial occupation his cardiac symptoms will cease.

Let us consider now the second form of rapid heart action, *paroxysmal tachycardia*. It is apparently due to rapid and regular waves of excitation and contraction arising at some point in the auricular or ventricular muscle outside the normal pacemaker. In this respect it resembles premature contractions of auricular or ventricular origin. Auricular paroxysmal tachycardia is a very frequent disturbance of rhythm but not quite so common as premature contractions. Various factors such as fatigue, undue or sudden exertion, alcohol, tobacco, coffee, digitalis poisoning, infection and heart disease are causes. Extraneous factors may be removed and the results watched. As with premature contractions heart disease is often absent. That is our problem—is there heart disease? Diseased hearts are more often the subject of auricular paroxysmal tachycardia than normal hearts. Auricular paroxysmal tachycardia is rarely seen in infants and young children. It is common in adults of all ages, especially in young adults and in the middle-aged. In the young adult *mitral stenosis* is frequently accompanied by auricular paroxysmal tachycardia and, indeed, may be one of the lesion's earliest signs. A mitral systolic murmur which could be passed as functional in an otherwise negative heart takes on a different aspect if there are occasional attacks of auricular paroxysmal tachycardia. Such a case should be studied carefully during normal rhythm to hear, if present, the middiastolic murmur of mitral stenosis. A few years ago I saw a healthy-looking married

woman, forty years old, with her physician. He had known her for many years and had never discovered any heart lesion. She had had 4 children, conducted her household and engaged in several outside interests. After an evening party she was awakened in the night by the rapid action of her heart. My examination resulted in little but the finding of a regular rhythm with a rate of 180. She did not know how the tachycardia began but its ending was sudden. Later I had an opportunity to examine her and found in the mitral area a distinct diastolic murmur. Two months later her physician asked me to see her when the tachycardia was repeated and a month later he telephoned that she was having another attack but I found that the arrhythmia was auricular fibrillation. About two months later she did not come down to breakfast at the usual time and her husband going to her room thought that she was profoundly unconscious. Her physician found a complete left hemiplegia which was followed by death in a few hours. Thus we saw the complete picture of mitral stenosis with its auricular paroxysmal tachycardiac, auricular fibrillation and cerebral embolus in regular order of sequence.

I have just seen a physician, thirty-seven years old, who has been strong and well all his life but rather nervous when going through an ordeal. For several years when bird hunting he has had attacks of rapid heart action just at the time of shooting a bird. The tachycardia comes on suddenly and ceases with equal suddenness. Recently the end of an attack has been characterized by a brief arrhythmia which has alarmed him and it was this feature which prompted the examination. Anxiety over a patient or nervousness when giving testimony during a trial by jury does not induce tachycardia. The physical examination was entirely negative. The electrocardiogram showed normal sinus rhythm with a rate of 92 for auricles and ventricles; the P-R interval was 0.12 second and the QRS 0.06 second; the T waves were upright in Leads I and II; there was no axis deviation and only slight slurring of the R waves. Here is the history of an intelligent man who has auricular paroxysmal tachycardia with abrupt onset

and offset but absolutely no physical signs of cardiac pathology. Furthermore, he does not have tachycardia except at the time of making a shot. One cannot take this single symptom, occurring rarely in an otherwise healthy individual, as anything very serious. Yet why does he occasionally have it while another apparently healthy man under similar circumstances does not? That is difficult to answer but it is plain that such a patient, like one with an unsolved murmur, should be observed from time to time.

### SYMPTOMS

In most instances the individual is conscious of a rapid rhythm; occasionally he is quite unaware of it as is also the patient with premature contractions; this sometimes occurs in the insensitive or the very ill. Generally these patients complain of a rapid palpitation or of a disagreeable fluttering in the chest and sometimes a pounding in the head, neck and even the arms and legs. Sensitive persons may have dyspnea and heart pain. In damaged hearts dyspnea may be present, especially in attacks lasting several days. Congestion of the lungs and liver and even of the extremities may occur due to prolonged inefficiency of ventricular contractions and because the brain for the same reason may not receive sufficient blood, vertigo and even loss of consciousness may ensue. In premature contractions with very prolonged compensatory pauses, and high degrees of heart block, faintness and syncope may be observed for the same cause.

### PHYSICAL SIGNS

When we are consulted by a patient with increased cardiac rate occurring in periods of varying duration the medical history must be carefully considered. If it is an increased rate due to and immediately following an infection it is readily disposed of, or if we can determine that the tachycardia is caused by some exertion or indiscretion that is clear to the patient or his physician, that too can be solved. Simple tachycardia which begins slowly, lasts a short time, ends slowly and occurs infrequently is usually an unimportant phenomenon.

Its rate may vary in the same individual under different conditions. Auricular paroxysmal tachycardia may be recognized clinically by its abrupt onset and offset, its rapid, regular rate varying from 110 to 200, lasting a few minutes, occasionally an hour, sometimes several days. It usually, unlike simple tachycardia, has a marked uniformity of rate. The blood pressure is often normal or slightly decreased and as might be expected because of the lessened output of the rapidly contracting ventricle, the pulse is small. Sometimes during very rapid action, especially if prolonged, pulsus alternans occurs due to muscle fatigue or occasionally intraventricular block develops. These are merely temporary manifestations and are easy to understand when we consider how such a rapidly moving heart must fail to maintain an even output due to regularly varying compensatory pauses or how with such rapid contractions the bundle can conduct all the small impulses. They are purely physiological disturbances of rhythm due to rapid rate and not to sclerosis or other disease of the cardiac tissues. The electrocardiogram employed during a paroxysm points to the area originating the attack but the instrument should be used after subsidence, to study any possible variations from the normal which may be obscured by the rapid rate and which may help in the discovery of cardiac disease. Quite often no other physical signs are found.

#### PROGNOSIS

If we can prove that the patient merely has simple sino-auricular tachycardia by history and physical examination, we can dismiss the symptom as one of unimportance. Indeed, auricular paroxysmal tachycardia is often dismissed in the same manner but let us analyze this symptom. If it begins in early life and is repeated at varying intervals, sometimes months or years, it is, like premature contractions, often harmless and of little consequence provided no signs of cardiac disease can be discovered. We have known of patients who have had attacks of tachycardia or premature contractions occurring at irregular intervals, some thirty, forty or even fifty years,

where no disease of the heart could be discovered and where its efficiency remained normal. On the other hand, if auricular paroxysmal tachycardia occurs frequently or is unduly prolonged, it may produce exhaustion and lead to chronic invalidism. We all have seen cases, as Lewis pointed out many years ago, where paroxysmal tachycardia tends to recur with shorter intervals until there is an attack which persists and ends fatally despite all our efforts. *Ventricular tachycardia*, a rare and often fatal sign, sometimes comes at the end of a clinical picture of heart failure but this is a result and not a cause. We have already said that in young adults auricular paroxysmal tachycardia is sometimes an early symptom of mitral stenosis and where there has been a history of rheumatic fever or repeated attacks of tonsillitis, it may precede auricular fibrillation. If one looks at the muscle damage and distortion about a stenosed mitral valve it is not difficult to comprehend why ectopic disturbances of rhythm occur. When auricular paroxysmal tachycardia begins in middle life, even if few or any signs of cardiac pathology can be discovered, it has always seemed to me of more significance. The same may be said of premature contractions. Nocturnal dyspnea, substernal oppression or pain, and tachycardia have seemed to me to be equally important and are indicative of a degenerated heart muscle laboring against anoxemia during the lowered cardiac rate of sleep. Such a heart may show very little during a routine examination and I am so afraid of missing the nocturnal symptoms which the patient may not voluntarily mention that I have the questions carefully indicated on my history sheets.

#### TREATMENT

Brief attacks of infrequent occurrence usually do not require treatment, although certain very sensitive individuals whose attention becomes focused on their hearts may have to have something done. Even though our physical examination may be entirely negative and our statements very encouraging, still the consciousness of cardiac action and of disturbed rhythm make treatment necessary in many cases. Prolonged

and frequent attacks demand an attempt to abolish them. Treatment therefore consists in an effort to stop an attack and to prevent recurrence. A very brief attack is usually over before much can be done about it. The prolonged attacks generally respond more readily if the patient is put at complete rest, seated or recumbent, although this is not always so and then some type of exercise, such as raising the arms above the head or bending the body, may abruptly end the attack. Some people learn that a change of posture will effect a cessation of the attack and immediately practice it. After the patient has assumed a satisfactory position and the attack continues, it is well to try carotid pressure which consists of firm pressure with the tips of two or three fingers on the carotid artery just above the clavicle for several seconds up to a minute. The pressure should be firm enough to occlude the artery but not enough to cause pain. If we fail on the right side, the left may be tried. I have done this many times but with frequent failure. Again firm pressure on either eyeball with the lids closed may be tried. These are very old procedures but are worth while. Induction of vomiting with ipecac is sometimes successful. I know one Boston physician who uses this method in preference to all others. Lunigo many years ago advised emetine for the same purpose. Firm abdominal pressure or an ice-bag over the cardiac area is sometimes helpful.

Drugs are not very reliable. With persons who are nervous or distressed, bromides, 15 grains every three or four hours, may be used or rarely morphine,  $\frac{1}{6}$  to  $\frac{1}{4}$  grain, subcutaneously. One should be cautious, however, about the use of the latter drug in a condition which may frequently repeat itself. Digifolin may be injected subcutaneously or, better still, intravenously. 12 grains every three or four hours for 4 or 5 doses. Of course the patient should be under the observation of the physician during this time.

The *prevention of auricular paroxysmal tachycardia* is quite as unreliable as the treatment of individual attacks. All of those factors which we have already mentioned as causes

should be sought for and eliminated. Then there is the added assurance of the physician who makes a careful physical examination and is able to encourage the patient with a statement of his negative findings. Digitalis or quinidine sulphate may be used. These drugs should be tried separately, giving digitalis the first place in doses of  $1\frac{1}{2}$  grains two or three times a day for a week and then  $1\frac{1}{2}$  grains daily for several months. The dose may be varied according to its effect upon the cardiac rate. If digitalis does not produce the desired effect, quinidine sulphate may be tried beginning with 3 grains, when, after waiting for five or six hours and being well borne, the dose may be repeated and then continued at the rate of 3 grains every two or three hours until a maximum daily dose of 18 grains is reached. After three or four days the dose may be reduced to 3 grains three times a day and so continued for several weeks.

Stepp and Schliephake in 1925 reported full and almost instantaneous control of paroxysmal tachycardia by using 0.5 cc. of a 5 per cent solution of choline chloride intramuscularly. More recently this drug under the name of Mecholyl (Merck) has been strongly recommended for intramuscular injection during the attacks. It comes in 10 cc. ampules, which may be injected into the muscle. It has also been given in the intervals in wafers of 1.5 Gm. each, which the patient can use himself.\*

#### DIFFERENTIAL DIAGNOSIS

Differential diagnosis is fairly easy. Sino-auricular tachycardia, paroxysmal tachycardia, auricular fibrillation and auricular flutter must be separated. Sino-auricular tachycardia has a gradual onset and offset and a variable rate, the latter often being evident during an attack, while paroxysmal tachycardia has a steady rate with abrupt onset and offset. The duration of auricular paroxysmal tachycardia is generally limited to a few minutes, seldom longer than two weeks, especially in the earlier attacks. A tachycardia which persists for

\* This paragraph was taken from a statement by the author in the *Jour. Amer. Med. Assoc.* Oct. 3, 1936, No. 14, Vol. 107, p. 1153

months or years suggests auricular flutter. The electrocardiogram will show the greatly increased auricular rate and a 2-1 auriculoventricular block. Ventricular is rare compared to auricular paroxysmal tachycardia and the electrocardiogram is necessary to separate them definitely, although slight irregularities of rhythm suggest the former. Auricular fibrillation can scarcely be confused with any other type of rhythm; its marked disorder is outstanding.

#### SUMMARY

We have endeavored to define the characteristics of sino-auricular tachycardia and auricular paroxysmal tachycardia and to indicate the difference in treatment.

It is highly essential to combine with our treatment as optimistic an outlook as possible, particularly when no signs of cardiac disease can be discovered, since the patient's anxiety over even a simple tachycardia may plunge him into a state of cardiac neurosis.

Ventricular paroxysmal tachycardia is not so common, is generally the accompaniment of serious cardiac disease and can be differentiated from the auricular type by the electrocardiograph. Also, a slight arrhythmia is more apt to occur in the course of the ventricular type but auricular paroxysmal tachycardia, usually very regular, may terminate in slight irregularity.

## CLINIC OF DRS. SOMA WEISS AND ROBERT W. WILKINS

THE THORNDIKE MEMORIAL LABORATORY, SECOND AND  
FOURTH MEDICAL SERVICES (HARVARD), BOSTON CITY  
HOSPITAL, THE DEPARTMENT OF MEDICINE, HARVARD  
MEDICAL SCHOOL

### SYNCOPE, COLLAPSE AND SHOCK: THEIR MEDICAL SIGNIFICANCE AND THEIR TREATMENT

#### SYNOPSIS

- I. Clinical features of congestive and noncongestive failure of the circulation.
- II. Syncope: clinical features; mechanisms; types.
- III. Treatment of syncope: specific measures; symptomatic remedies.
- IV. Collapse and shock: clinical features; mechanisms; types.
- V. Combined occurrence of congestive heart failure with collapse and shock.
- VI. Treatment of collapse and shock:

#### Specific measures.

1. Supply of deficiencies (water, salt, blood, oxygen, protein, glucose and heat).
2. Elimination of abnormal factors (sleeplessness, fear, pain, "toxins" and chemical substances).

Symptomatic measures (shock position, blood transfusion, glucose, sucrose, gum of acacia, strychnine, caffeine, coramine, cardiazol, ephedrine, benzedrine, epinephrine, synephrine).

VII. Summary.

VIII. Bibliography.

#### 1. CLINICAL FEATURES OF CONGESTIVE AND NONCONGESTIVE FAILURE OF THE CIRCULATION

Failure of the circulation is still considered by some as being synonymous with heart failure; hence efforts to treat this condition often consist in attempts to improve the function of the heart. In the daily practice of medicine, as a matter of fact, general circulatory failure of noncardiac origin

is as common as, if not more frequent than, circulatory failure of cardiac origin. When confronted with a patient with evidence of acute failure of the circulation, physicians should always attempt to answer the following questions: (1) Is the deranged state of the circulation primarily (a) of the congestive type ("backward" failure) or (b) of the noncongestive type ("ischemic," "hypokinetic," "forward" failure)? (2) Is it primarily of cardiac origin? (3) Is it primarily of peripheral vascular origin ("ischemic failure," "peripheral syncope and collapse" or "shock")? (4) Is it primarily a loss of blood volume ("collapse" and "shock")? (5) Finally, is it, as often is the case, a combination of these factors? If, through analysis of the symptoms, signs and technical measurements, these questions are answered correctly, the treatment of circulatory failure will be more successful; more lives will be saved or prolonged, and under any condition comfort will be brought to the patients.

Therapy will depend on which of these conditions exist. Indeed, *in different types of circulatory failure the therapeutic approach may be diametrically opposite*. Thus, a patient with air hunger due to a desperate attack of cardiac asthma will be relieved by venesection, whereas a patient with air hunger due to shock may die as a result of such a therapeutic procedure. Indeed, since the time of Hunter, Cooper and Broussais much harm has been done through indiscriminate use of bloodletting in circulatory failure. In instances in which a combination of types of circulatory failure are present, sound judgment and extreme caution are needed. Here, as in other therapeutic problems, "skill" and "art" are but the summation of rational clinical analysis (diagnosis) and synthesis (treatment).

Circulatory failure of the congestive type is always of cardiac origin and is usually spoken of as "cardiac failure." It is important to bear in mind, however, that heart failure may be of the noncongestive as well as of the congestive type. The chief characteristic of *congestive* failure is engorgement of the venous system, either in the pulmonary circuit or in the larger systemic circuit. The *clinical features are due to*

venous engorgement with resultant elevated capillary pressure and opening of reserve capillaries, and to tissue responses secondary to these circulatory changes.<sup>1</sup> Thus, dyspnea, orthopnea, Cheyne-Stokes' respiration, arterial anoxemia with cyanosis, pulmonary râles and edema, and, at times, hydrothorax are the usual manifestations of pulmonary engorgement; while distended superficial veins, cyanosis associated with increased oxygen utilization, dependent edema, hydrothorax, ascites, tender and enlarged liver and other manifestations of passive congestion of viscera are results of engorgement of the veins and of increased capillary pressure of the larger circuit. Clinically, in a given patient one usually finds evidence of a disproportionate congestion of the pulmonary circuit or of the larger systemic circuit. This is due to the fact that the lesions which result in congestion are usually localized in one side of the heart, and throw a strain predominantly on either the left or the right ventricle. This has led to the use of the terms "*left ventricular failure*," to describe cases in which the pulmonary circuit is engorged, and "*right ventricular failure*," to describe those in which the systemic circuit is engorged.

In congestive failure the arterial pressure may remain unchanged or may become lowered or elevated. The blood flow through the heart may be normal or decreased, and a normal or fairly normal peripheral circulation may be present, even in grave cases.<sup>1, 2, 3</sup> The velocity of flow through the individual pulmonary pathways is, however, reduced as a result of increased cross-sectional diameter of the capillary system due to venous engorgement.<sup>4, 5</sup> The circulating ("effective") blood volume is usually increased, and the total blood volume always increased,<sup>6</sup> in chronic congestive failure. This represents an important compensatory mechanism and a safeguard against collapse and shock.

Heart failure of the *noncongestive* or "anoxic," "ischemic" type is due to acute impairment of the heart as a whole, which results in a totally inadequate output of blood. Examples of this "forward" type of heart failure are found in the sudden

arrhythmias and asystoles, or in the more prolonged toxic, infectious or degenerative myocardial failures, such as occur in diphtheria or in senility. In such cases the manifestations usually present in congestive failure often do not occur, or are of mild degree and evenly distributed within both circuits. The total blood volume is unchanged, but the circulating volume is diminished. The large reservoirs of the greater circulation take up considerable amounts of blood, and manifestations of venous engorgement are absent or occur late.

The noncongestive type of circulatory failure is more frequently of *noncardiac* than of cardiac origin. It then results from a *disproportion between the total blood volume and the total vascular volume, and is accompanied by a reduction of the circulating ("effective") blood volume*. Either the total vascular volume increases, or the total blood volume decreases, or both changes occur simultaneously. The total vascular volume may be increased by the dilatation of vessels already open or by the opening up of vascular areas hitherto closed. The total blood volume may be decreased by hemorrhage, dehydration or diffusion of plasma as a result of various hemic or vascular changes. In any case, the result is a decreased return of blood to the right side of the heart and hence a diminished circulating ("effective") blood volume, a decreased cardiac output, lowered arterial and capillary pressures and, finally, anoxia of certain tissues.

It is the purpose of this discussion to emphasize the following considerations: (1) syncope, collapse and shock represent the same type of circulatory disturbance characterized by an *acute noncongestive* ("anoxic," "forward," "ischemic") failure of the circulation, associated with anoxia of certain tissues, particularly of the brain. (2) All three of these circulatory syndromes may be caused by many different mechanisms, but they are all similar or identical in nature. (3) The essential differences between the circulatory states in syncope, collapse and shock are quantitative rather than qualitative. All three syndromes are stages or degrees of the same fundamental type of circulatory failure, but with different

bodily effects and prognosis. (4) To search for a single cause of syncope, collapse or shock is to acknowledge lack of understanding of the problem as observed at the bedside. (5) For the correct therapeutic management, knowledge of the exact mechanisms of each of these syndromes is essential. The diagnosis of "syncope," "collapse" or "shock" is inadequate because treatment should always attempt to correct the specific cause, and only secondarily to improve the circulatory state through symptomatic measures.

## II. SYNCOPE

Syncope is a remarkable example of the noncongestive ("anoxic," "forward") type of failure of the circulation precipitated by nervous, cardiac or vascular factors. It is an acute and usually transient bodily state associated with sudden, partial or complete cessation of the circulation, with loss of power of locomotion and loss of consciousness. There are a number of associated manifestations involving practically every system of the body. The symptomatology and mechanisms of the various types of syncope have been described elsewhere.<sup>7</sup> The main characteristics of the circulatory state consist in a sudden fall of the arterial and capillary flow and pressure, and a decreased return of blood to the right ventricle. The veins usually are collapsed. As a rule the circulation within the central nervous system is particularly disturbed. One sees the manifestations of acute cerebral anoxia in its pure form. Attacks of syncope usually last only a few seconds or a few minutes. Because of their short duration, usually no after-effect is observed following recovery. As a result of the intensity of the changes, on the other hand, the manifestations are alarming, and in rare cases death may occur.

There are several types of factors which, singly or in various combinations, play a significant rôle in syncopal attacks: *cardiac* disturbances, such as vagal inhibition, angina pectoris, coronary thrombosis, dissecting aneurysm, heart block, and paroxysmal tachycardia; *vascular* derangements, such as postural hypotension, vascular crisis of hypertension;

*chemical* agents, such as sodium nitrite, nitroglycerin, anaphylactic, bacterial toxins; *reflex* mechanisms, such as vasovagal, vagovagal, carotid sinus, oculocardiac, pleural and pericardial reflexes; and *psychic* factors, as in vasovagal neurosis, Gowers' and Nothnagel's syndromes. Syncope is one of the most striking examples of the widespread and serious influence of psychic factors on the functions of various vital organs. In a somewhat arbitrary manner, depending on the underlying mechanism, we have differentiated some 16 types of syncope.

The studies reported previously<sup>8, 9</sup> indicate that unconsciousness associated with syncope usually is due to a sudden diminution of the cerebral circulation. A close correlation between the degree of ischemia and unconsciousness does not always exist, however, mainly because the simultaneous activity of reflexes frequently exerts a direct effect on the centers regulating consciousness. It is of interest that the same afferent nervous mechanism which is active in carotid sinus syncope is capable of producing attacks of unconsciousness of cardiac, vascular or direct central reflex origin, singly or in combination. Certain types of attacks of unconsciousness observed in syncope represent transitional states between unconsciousness of primary cerebral origin, usually associated with convulsions (fits), and unconsciousness of systemic circulatory origin (faints), often accompanied by milder seizures. We have emphasized elsewhere<sup>7</sup> the fact that the differential features of fits and faints frequently are more relative than absolute.

Syncope may occur in otherwise healthy persons and in persons who are gravely ill. In the majority of instances it is a benign, transient manifestation, but not infrequently, particularly in organic diseases, it may be fatal. Instances of fatal cardiac syncope are particularly common in patients with coronary disease. Such fatal attacks are apt to occur in the upright position during exertion. In cases of coronary sclerosis postmortem examination frequently fails to reveal the immediate cause of death. In this disease, as well as in coro-

nary thrombosis, there is present a considerably increased vagal reflex inhibition, as well as a tendency to ventricular ectopic beats and to ventricular fibrillation. Sudden death occurring within a few seconds in previously healthy subjects is usually due to ventricular fibrillation or, rarely, to sudden cardiac standstill. We have observed three instances of sudden cardiac syncope in apparently healthy and vigorous young persons who were recovering from an ordinary respiratory infection. Postmortem examination in one instance indicated that the cardiovascular system was normal. Fatal cardiac syncope may occur in elderly persons when they start to walk after prolonged bed rest. Postmortem examination again throws no light on the cause of death in such cases. Apparently we are dealing with a fatal vasovagal syncope in persons with unstable vasomotor mechanisms and with increased vagal tone.

The essential difference between syncope in the normal and in the diseased man lies in the ability to reestablish normal equilibrium. Whereas in normal subjects, owing to the presence of numerous emergency functions and to the reserve capacity of the organs involved, a return to the normal equilibrium is accomplished with relative ease and promptness, in diseased persons, on the other hand, because of damaged systems, a return to the normal level is more difficult, is usually slower, or may even not occur. Whenever death occurs unexpectedly and within a few seconds, the most probable cause is syncope and not acute organic lesions, such as cerebrovascular accident or coronary thrombosis.

The primary danger from syncope is its damaging effect on the central nervous system. With the decreased return of blood to the right side of the heart not only is the volume of blood flow decreased, but such blood as flows to the organs and particularly to the brain must be under unusually low pressure in the capillaries. The circulation in syncope is markedly influenced by gravity. Hence the circulatory disturbance is particularly severe in the orthostatic position, and the maintenance of this position is a serious threat to the patient's life.

## III. TREATMENT OF SYNCOPE

**Specific Measures.**—In the majority of instances of syncope, regulatory mechanisms of the body (autotherapy) take care of the condition. A close correlation exists between circulatory changes associated with syncope and the function of centers which promptly induce unconsciousness and relax voluntary muscles. Thus fainting, or falling to a prone position, associated with mild clonic convulsive movements, serves a twofold purpose: (1) the sensitive structures of the central nervous system are brought down from a "high ischemic level" to the level of the heart; and (2) the return of blood to the heart is made easier in the horizontal level, and is then further aided by the convulsions.

Selection of specific therapeutic measures depends on a knowledge of the underlying mechanism of syncope. In some instances of vasovagal syncope, psychic conflicts represent the trigger mechanism, and proper eradication of the emotional difficulties often results in abolition of the attacks. In cases of congenital or acquired loss of tone of abdominal vessels, proper mechanical supports may be effective. Ephedrine in doses of  $\frac{1}{4}$  to  $\frac{1}{2}$  grain (15 to 30 mg.) two or three times daily also may be useful. Reflex syncope, such as the carotid sinus, vagovagal, pleural and pericardial syncopes, may be abolished or prevented by surgical section of specific afferent nerves, or by application of local anesthetics over the nerve endings irritated during surgical manipulations. In the prevention of syncope associated with postural hypotension, abdominal supports, elastic stockings, ephedrine and ergotamine are useful. Some of the postural hypotensive syncopes are related to lues of the central nervous system or to anemia, and in such instances the specific treatment of these conditions will abolish the attacks. Syncope of central vasomotor origin such as occurs after the administration of local anesthetics, can be prevented or abolished by the barbituric acid derivatives and other drugs which decrease the lability of the vasomotor centers. In the abolition of syncope associated with bradycardia (Adams-Stokes attacks), epinephrine or ephedrine is

of great value. The prevention or abolition of syncope caused by tachycardia depends on specific treatment of paroxysmal auricular or ventricular tachycardia, or of auricular or ventricular fibrillation. Syncope associated with heart failure is to be treated by measures which improve the cardiac function. If syncope results from acute loss of blood, prompt restoration of the blood volume is the most efficacious measure.

**Symptomatic Treatment.**—If the exact mechanism of syncope is not known, or if specific measures cannot be instituted, the attacks should be managed symptomatically. This is particularly essential if a patient is in an acute attack. The immediate danger in syncope is cerebral and cardiac ischemia. One of the simplest measures for facilitating return of blood to the heart and hence to the brain is to place the body in a horizontal or "shock position" (Trendelenburg's position). Additional elevation of the legs and their massage, associated with cardiac and thoracic massage, may be of considerable help. If examination of the heart indicates that vagal inhibition is a factor, atropine, alone or with epinephrine, will be of aid. Similarly, in instances of bradycardia, epinephrine, ephedrine and benzedrine will raise the cardiac rate and functional capacity. If there is evidence of a marked fall in pressure without bradycardia or asystole, epinephrine is the drug of choice. If in acute emergencies epinephrine is given intravenously or intracardially, relatively small doses, such as 0.5 cc. of a 1:10,000 solution, should be given.

#### IV. COLLAPSE AND SHOCK

In patients who are suffering from serious diseases but whose circulation has hitherto been normal or at least adequate, one frequently observes a sudden, unexpected elevation of the cardiac rate associated with a fall in the arterial pressure and a change in the clinical behavior of the patient. The patient becomes anxious and restless, the face appears pale or ashen, and usually is covered with perspiration. The skin as a rule is cold, but it may at times be warm. The patient is unconscious and will respond, but the sphere of interest rapidly

narrows and cloudiness of sensation develops. Impairment of mental acuity encroaches on the patient without his being aware of it. After recovery, there may be amnesia of events occurring during collapse. If the collapse is severe the radial, dorsalis pedis and other peripheral arterial pulsations are thready or imperceptible, while the carotid and other centrally located arteries exhibit a high bounding but empty pulsation. Subsequently cyanosis of the cold fingertips and toes may advance toward the trunk. The veins are collapsed and the pressure in them is low. The blood flow through the heart and other organs is greatly diminished. The circulation becomes more susceptible to the influence of gravity, and the return of blood to the right side of the heart is greatly affected by changes in position. The respiration is quiet and shallow, or deep and somewhat slow, but there is no orthopnea. Frequently, as in syncope, there are manifestations of disturbance of certain vegetative centers. Sudden vagal inhibition manifested by cardiac slowing, gooseflesh, pyloric spasm, nausea, vomiting, acute dilatation of the stomach and perspiration may occur. Many of these symptoms are due to an irritative response to certain centers to acute anoxia (*syndrome of acute cerebral anoxia*). The significant rôle of the cerebral circulation in collapse and its relation to posture are shown by the behavior of patients who, when propped up in bed, promptly fall into stupor, but when placed in shock position at once regain consciousness. We have had opportunity to make repeated observations on the striking differences in the psychic and bodily responses of such patients in these two positions.

This condition of circulatory *collapse* usually lasts but a few minutes to a few hours. When recovery occurs the patient looks normal within a short time. In protracted and ultimately fatal diseases, as in sepsis, spontaneous recovery usually follows the first attack of collapse. Subsequently, however, not only are attacks apt to recur with increasing frequency, but each attack is of longer duration and responds less to medication. During one of these attacks death may occur rather unexpectedly.

It is also a common occurrence for a similar type of circulatory derangement to persist for many hours, or even for several days, with varying degrees of fluctuation. Such a circulatory state is usually called *shock*.\* The onset may be either insidious or sudden. The initial behavior of the circulation may be identical with that in collapse, or there may be a preliminary stage when the circulation is apparently overactive, with the color good, the skin warm, the pulse bounding, and the heart action snapping and vigorous. This is frequently seen in infections, deficiency disease, delirium tremens, cerebrovascular accidents, spinal anesthesia and traumatic conditions. Measurements indicate that the arterioles, at least in some organs, are dilated, but the low blood pressure readings suggest that the effective circulating volume even at this stage is reduced. Subsequently, however, certain significant changes occur. The patient becomes profoundly pale and his eyes gradually sink in their sockets, giving him an anxious expression. The nose and face appear pinched. The voice is feeble and hoarse. Movements of the body progressively decrease and there is general prostration. The body temperature may be elevated initially, but subsequently it gradually becomes subnormal. The patient loses interest in his surroundings, but if aroused he responds with exaggerated intensity, although vaguely. In this late stage, even if the blood pressure and circulating blood volume are reestablished, improvement in the patient's general condition usually lags behind, or often does not follow.

\* The use in the literature of the terms "collapse" and "shock" is confusing because of the various implications of these names. Many authors use the terms interchangeably. Some observers, however, describe as "collapse" a circulatory disturbance characterized principally by cold skin, cyanosis and a rapid feeble pulse, and as "shock" a syndrome with warm skin, good color, and bounding empty pulse. We agree that those two types of manifestations exist, but we believe that a differentiation between them is only of secondary importance as they represent but subdivisions or stages of the more fundamental disturbance which we call "collapse" and "shock." Regardless of what terms are used in this problem the emphasis should be placed, not upon the name of the disturbance, but upon the recognition and understanding of the underlying disturbance.

The main characteristic of the circulation in both collapse and shock is a decrease in the circulating ("effective") blood volume. In both states there is usually a diminished return of blood to the right side of the heart, associated with rapid heart rate, low arterial, venous and capillary pressures, and progressive stagnation of blood in certain vascular areas, usually in the "blood depots." Not all these features, however, are present in each case, or in each stage of the two syndromes. *The essential differences between collapse and shock consist in the time element of the circulatory disturbance and in the severity of the chemical and functional changes in the tissues.* In collapse the circulatory failure is usually of shorter duration, the changes are still primarily within the cardiovascular system, and the dysfunction may rapidly revert toward normal. In shock, on the other hand, owing to the long duration of circulatory failure, changes develop within the tissues, particularly in the central nervous system, and consequently a return toward a normal state is more difficult and slower.

In shock, as in collapse, blood may be pooled in various vascular areas. Depending on the nature or location of trauma, on the chemical agents, or on nervous factors involved, these "pooling" areas may be generalized or may be localized in only one extremity, in the skin, or in the abdominal viscera. The dilatation of the small veins and venules of many organs plays a particularly important rôle.<sup>10, 11, 12</sup> These vessels possess great active as well as passive capacity to alter their lumens. It is of interest that dilatation of these venous vessels often coexists with constriction of the arterioles.<sup>12</sup>

As a result of the persistent ischemic capillary circulation, producing anoxia of tissues and the accumulation of local metabolites, changes in the capillary permeability may occur in some or in all organs, with consequent loss of blood plasma into the tissues, which further aggravates the condition.<sup>11</sup> Unless there is acute hemorrhage, hemoconcentration follows. Judging from the clinical and postmortem findings, edema and dehydration of different organs may coexist, particularly if the development of shock is gradual. Apparently, on the one hand

plasma oozes from the blood into the tissues where there is damaged capillary permeability and, on the other hand, tissue fluids return to the blood from organs with normal capillary permeability. Thus, provided there is adequate fluid intake, one may see patients with peritonitis or with advanced diabetic collapse who have a dry tongue and sunken, soft eyes, and a dehydrated blood, coexisting with edema of the lungs and buttocks and free fluid in the serous cavities. The altered chemical nature of the alveolar and pleural fluids, as well as the reduced plasma proteins and elevated red cell counts in such cases, indicates that an appreciable amount of fluid enters into the tissues from the blood. The damaging effect of this process of transudation must be an important factor, though little definite information is available on this phase of the problem.

Great individual variation exists in the tendency to collapse and shock. Elderly persons, and patients with previously diseased cardiovascular systems develop collapse and shock under less strain and damage than do young, healthy persons. Furthermore, as judged from clinical observation, persons of the same sex and the same age group differ in their capacity to withstand damaging stimuli to the vascular system. Infectious diseases, chemical poisons, physical trauma and nervous stimuli of the same intensity produce fatal collapse or shock in one group but not in another. One is impressed at the bedside by the capacity of certain individuals to withstand severe, persistent "battering" of the vascular system by toxic, nervous and traumatic stimuli. The decisive factors in this variation in the susceptibility to collapse or to shock are the innate state of the nervous centers and reflexes, the "vascular tonus," and the "vitality" of the tissues in general.

The onset of shock is often gradual and insidious, with slow fluctuations, but with a steady downhill tendency toward the profound changes which precede death. Both collapse and shock may, however, appear with dramatic suddenness in the course of long-existing disease, especially in aged

persons, causing death within a few hours. Such collapse often develops without alteration in the intensity of causative factors. Apparently the nervous system and the cardiovascular system can stand but a given amount of total "bombardment" by abnormal impulses. When the limit is reached, rapid disintegration follows. Whether this is preceded by a progressive decrease in the "vasomotor reserve" is not definitely known. Evidence is available, however, that a progressive "exhaustion" of the vasomotor system is counterbalanced by numerous regulatory adjustments until the final "break" appears clinically.

As far as the circulatory changes are concerned, the difference between syncope, collapse and shock is mainly one of degree, as is demonstrated by the fact that the same *causes* and *mechanisms* produce syncope, collapse or shock, depending mainly on the duration of the attack. Thus, pleural shock from a spontaneous pneumothorax may cause only transient unconsciousness with hypotension and tachycardia of but a few seconds' duration (syncope), or it may cause the same type of circulatory changes of milder intensity but of longer duration, resulting in general prostration of several hours' duration (collapse or shock). When a patient with an infectious disease suffers from circulatory collapse even while in the horizontal position, syncope with unconsciousness and serious disintegration of the circulation may follow if an upright position is suddenly assumed. It is also of interest in this connection that when administered to normal subjects, sodium nitrite may induce syncope, collapse or shock, depending on the dosage administered and on the degree of tilting of the body. An analysis of the circulatory changes in such subjects reveals the same type of disturbances as occur in diseased persons. This again demonstrates that a single type of circulatory failure may have entirely different prognostic significance, depending on its *duration*, and particularly on the preexisting state of the cardiovascular and nervous systems.

The *causes* of collapse and shock are identical and they are numerous. Psychic and nervous factors, chemical agents

trauma, hemorrhage, dehydration, singly or in various combinations, are capable of inducing these states. The majority of chemical and nervous factors act on the peripheral circulatory system, producing dilatation, paresis and changes in the permeability of the minute vessels of various organs of the body. Other factors, however, act primarily on the "vasomotor" centers and hence indirectly influence the volume of the vascular bed. In the early stage of collapse and shock the disproportion developing between vascular volume and blood volume is compensated by regulatory adjustments, mainly through reflex mechanisms and the action of local metabolites. Subsequently, however, primarily as a result of anoxia of the central nervous system, these and other regulatory mechanisms begin to fail, and rapid disintegration of bodily functions follows.

In disease of the internal organs, such as occurs in the field of clinical medicine, neurogenic factors play a significant rôle, operating through afferent nervous impulses. It is known that afferent impulses, especially from the viscera, traveling through sympathetic and parasympathetic nerves, are particularly responsible for vasodilatation, shunting of blood and lowering of the circulating ("effective") blood volume. Afferent impulses from somatic nerves, on the other hand, are apt to cause a rise in blood pressure (Loven reflex). In previous studies, examples have been presented demonstrating that afferent impulses from a single branch or from branches of the sensory-vagus or sympathetic nerves may, in the presence of pathogenically hyperactive reflexes, produce instantaneous syncope or collapse (vasovagal, vagovagal, carotid sinus, oculocardiac, pleural, pericardial types).

It is essential to appreciate that *the level of the arterial pressure alone is not a decisive characteristic of the clinical severity of collapse or shock*. A patient with arteriolar vasodilatation of neurogenic origin may exhibit low arterial pressure but nevertheless may have a more effective capillary flow through the vital organs than a patient with normal arterial pressure accompanied by maximal arterial and ar-

teriolar constriction, also of neurogenic origin. In the latter instance the blood flow through the capillaries may be quite inadequate for tissue nourishment. In both instances, in spite of the opposite behavior of the arterioles, there may be considerable dilatation of the venous reservoirs. The collapse of fever is an example of the former type, while collapse due to sodium nitrite is an example of the latter type.\*

Collapse and shock may originate in a disturbance of the heart or of the peripheral vascular system; in either case failure of the central nervous system occurs secondarily, and this, in turn, further accentuates the circulatory failure. In other instances, collapse and shock originate in the central nervous system as a result of disturbance of the vasomotor centers, through pain, psychic factors, such as fear, local anesthetics, hypnotics and cerebrovascular accidents. Changes in the peripheral vessels and in the blood volume then develop, which so decrease the cerebral circulation that further depression and failure of the already disturbed nervous functions result. *Regardless of the original cause of collapse and shock, this type of failure of the circulation represents a tendency to a vicious circle in which the vascular reactivity and blood volume, on the one hand, and the central nervous system, on the other hand, are in close interrelationship.* In a given case of collapse or shock one or another of these factors may predominate.

In addition to the central nervous system, the functions of the kidneys and other organs will become impaired. As a result of low arterial pressure and concentrated small "effective" blood volume, renal function rapidly decreases and complete anuria often follows. This, in turn, leads to a disturbance of the acid-base equilibrium, which adds one more factor to the

\* It is often assumed that change in cardiac rate and fall in arterial pressure are reliable indications of impending collapse. This, however, is frequently not the case. In elderly patients, in particular, the change in the facial appearance (dropping of the facial lines), retardation and confusion of mental processes, stertorous breathing, cyanosis, pallor and perspiration clearly indicate to the experienced physician the onset of collapse at a time when the arterial pressure is still unaltered and the heart rate but moderately elevated.

vicious circle. In a similar way the disturbed function of other vital organs, notably the liver and the gastro-intestinal canal, may add to the increasing state of depression of the vital processes.

Collapse and shock are often designated after the causative agent or disease; for example, "traumatic," "hemorrhagic," "infusion" or "speed," "anaphylactic," "hemoclastic," "colloidal," "dehydration," "bichloride of mercury," "diabetic," "pneumonia," "barbiturate," "renal," "histamine." These terms, however, are of little value to the physician unless he understands the mechanism underlying each form. Often several types of collapse may occur under a single designation. In the collapse of pneumonia, for example, dehydration, fever or vasodilating substances (bacterial toxins), singly or in combination, may be the causative factors. Similarly, in diabetes, tissue acidosis, dehydration, loss of electrolytes and infection may be responsible for collapse. The treatment of the various types of collapse and shock will depend on which of these factors are responsible.

The designation of "primary" collapse and shock to indicate the acute circulatory failure of nervous origin, and "secondary" collapse and shock to indicate a similar state of the circulation in which chemical agents, bacterial toxins, anesthetics, trauma or hemorrhage are the causative factors, is not entirely justified. There is no evidence that there is an essential difference in the circulatory failure in "medical" and in "surgical" shock.<sup>14</sup> These terms at best serve but for the designation of types of shock occurring in medical and surgical conditions. In both types, hemorrhage, dehydration, and vasodilator, vasoparetic and central depressant factors are active and the various mechanisms leading to failure of the circulation must be determined. In the field of internal medicine collapse and shock play a more important rôle than in surgery. It is quite remarkable, therefore, that their various forms have not heretofore been studied in clinical medicine.

## V. COMBINED OCCURRENCE OF CONGESTIVE HEART FAILURE WITH COLLAPSE AND SHOCK

In the foregoing discussion it has been shown that nervous and vascular factors without heart disease are frequently responsible for disintegration of the circulation. We should like now to emphasize that the acute noncongestive ("anoxic," "forward") type of failure of the circulation often appears in combination with the congestive type of failure. Whenever a *previously healthy or compensated heart fails acutely, the clinical picture will be a combination of congestive failure and collapse or shock.* As was pointed out before, the features of collapse and shock often predominate. As a result of failure of the ventricles a large volume of blood is suddenly shunted into large venous reservoirs, and the arterial and capillary systems become acutely deprived of blood. Under such conditions the danger to the organism will be particularly enhanced if simultaneously active dilatation of the arterioles, capillaries and venules suddenly occurs, as a result of pain or some other factor. In studying the behavior of the hemodynamics of animals one frequently has opportunity to observe the "see-saw" effect of a cardiotoxic agent on the arterial and venous systems. Following the injection of such substances as heavy metals, hypnotics or arsphenamine, or following manipulation or acute anoxia of the heart, there is a rapid rise in the venous pressure in the left and right auricles and a sudden fall in the arterial pressure. As soon as the cardiac damage is rectified the elevated venous pressure falls and the arterial pressure returns to the normal level. In man, a similar type of circulatory disturbance is observed in acute cardiac accidents: after coronary thrombosis, during the administration of anesthetics, during surgical manipulation of the heart and during certain arrhythmias. Such patients exhibit orthopnea, pulmonary edema, air hunger, distended veins, rapid thready pulse, anxiety, and cold skin with beaded perspiration. If venesection is undertaken on such patients, we have observed that after the removal of not more than 200 or 300 cc. of blood frank signs of collapse may come to the surface. We should

like to point out also that when cardiac patients suffering from chronic congestive failure develop collapse and shock, the manifestations of congestive heart failure and venous engorgement often subside or even disappear, in spite of the fact that the impairment of cardiac function persists. We have had opportunity to note that in patients with chronic congestive heart failure due to rheumatic and syphilitic heart disease, during collapse and shock the orthopnea and dyspnea improve and the venous pressure approaches normal. This mechanism may even be life-saving in certain extreme attacks of cardiac asthma. In this condition there are manifestations of marked left ventricular failure associated with acute pulmonary engorgement. In the severe and prolonged attacks, manifestations of collapse are often added to the clinical picture of cardiac asthma, and the patient appears to be in extremis. Usually, however, it is at this very stage that spontaneous improvement sets in and the symptoms and signs of pulmonary engorgement subside. The distress of the attack has produced a secondary collapse, which in turn acts as a venesection. This is, then, one of the numerous instances of autotherapy of the body.

#### VI. TREATMENT OF COLLAPSE AND SHOCK

From what has been said of the mechanisms of collapse and shock, certain general conclusions as to the principles of treatment may be drawn: (1) treatment should be aimed at the elimination of the causative agents. (2) Treatment should as far as possible be preventive, or should be instituted early. In shock, in contrast to syncope and collapse, one deals with secondary changes within the tissues which cause a tendency to irreversible or difficultly reversible processes; one may therefore reestablish the circulating blood volume and the blood pressure with only slow or no recovery of the patient.

3. Symptomatic treatment of shock is of only temporary benefit, but it is of value in helping the patient during the period when the etiological factor is being eliminated.

**Specific Measures.**—The success of specific therapy will depend on the nature of the collapse and shock. Usually

attacks of collapse and shock due to the deficiency of essential intrinsic bodily factors are treated more successfully than those due to the presence of abnormal factors. In the "deficiency types of shock," water, electrolytes, blood, oxygen, protein, glucose and heat play particularly important rôles.

1. *Supply of Deficiencies.* (a) *Water and Salt.*—There is a remarkable tendency of the body to maintain the salt concentration at an even level both in the blood and in tissue spaces. When water is lost, elimination of salt follows, and vice versa. Hence the lack of these two substances is closely related and plays an important rôle in the causation of shock associated with many diseases. This has been emphasized recently by Atchley and Loeb.<sup>16</sup> The normal daily output of water in health is about 2 to 3 liters, and of sodium chloride, 15 Gm. In diseases associated with fever or with fistulous opening, but particularly in conditions associated with diarrhea or with vomiting, the water and salt loss may be considerably increased. It has been estimated that normally between 7500 and 10,000 cc. of fluid are secreted into the intestinal canal within twenty-four hours.<sup>16</sup> Whereas in health the greater part of this fluid is reabsorbed, in pathological conditions, particularly those associated with vomiting and diarrhea, most of it, together with its organic and inorganic constituents, may be lost. Unless corrected, such a fluid and salt loss rapidly leads to a reduction of the blood volume with hemoconcentration, and hence to collapse and shock. Collapse and shock of dehydration may also result from the indiscriminate use of gastric or duodenal drainage with suction, such as is in vogue at present in various surgical and medical conditions often already associated with a tendency to collapse and shock. We have observed instances of abdominal distention in which constant gastric suction produced the typical syndrome of dehydration shock. In the majority of instances of "diabetic collapse," of collapse and shock occurring in infectious diseases, in heat exhaustion, in adrenal insufficiency, and in biliary and pleural fistulas, water and salt deficiency are significant if not the sole precipitating factors. In these con-

ditions, therefore, a constant effort should be made to prevent such deficiency by the subcutaneous or intravenous administration of from 1000 to 2000 cc. of normal saline solution three or four times daily. In severe cases of collapse and shock the intravenous route is always the choice, as in these states fluid is poorly absorbed from subcutaneous depots as well as from the gastro-intestinal canal. It is important, however, that intravenous infusion should be performed slowly in order to avoid embarrassment to the heart. The normal heart can take care of the slow intravenous infusion of from 7000 to 10,000 cc. of fluid in twenty-four hours. If there is a possibility that the cardiac function is impaired, clinical estimation or actual measurements of the venous pressure should be performed. If the pressure rises above 10 cm. the infusion should be slowed or stopped temporarily. An average rate of 10 cc. a minute, or 1000 cc. in one and one-half hours, should be maintained. In case there is indication that loss of salt is the primary cause, 2 to 3 Gm. (30 to 45 grains) of salt can be given orally or parenterally in concentrated solution three times daily.

(b) *Blood*.—In patients with severe hemorrhage, blood transfusion promptly alleviates collapse. Blood transfusion may also be used as a symptomatic remedy to increase the circulating volume and elevate the arterial pressure. Infusion of whole blood rather than of a crystalloid solution is particularly indicated in the type of collapse and shock accompanied by increased permeability of the capillaries. In certain types of shock, however, even proteins and whole serum may leave the vessels and pass into the tissues.

(c) *Oxygen*.—Anoxia of tissues is of fundamental significance in collapse and shock. In certain types of collapse, such as the collapse associated with coronary thrombosis, emphysema, bronchial asthma, pulmonary embolus, pulmonary edema, and high altitude (mountain sickness or aviation collapse), lack of oxygen in the tissues plays a specific rôle. Such anoxia is due either to the fact that oxygen has difficulty in diffusing through the alveolar walls into the blood (anoxemia) or to the

fact that the oxygen is unable to diffuse from the blood into the tissues (anoxia) because of its low partial pressure. At an altitude of 4500 meters the saturation of the arterial blood is still 85 per cent, but the oxygen partial pressure drops from 100 to 50 mm.<sup>17</sup> In these types of collapse and shock the administration of oxygen results in rapid improvement.

(d) *Protein*.—Because in shock there is a tendency toward increased capillary permeability, loss of fluids into the tissues will be even greater if there is a low protein level of the blood. The latter, therefore, enhances the disintegration of the circulation. An effort should be made to maintain the proper level of blood proteins through good nutrition or through transfusion. That loss of serum may occur through open wounds or burns is well known. Less well known is the fact that repeated abdominal and pleural taps can deplete the protein and electrolytic content of the blood. We have observed cases in which the circulatory collapse and fatal shock occurring in association with cirrhosis were directly traceable to the repeated removal of fluid rich in protein and to the inability of the body to replace the loss. A simple calculation of the protein content of the fluids removed will indicate the severe draining effect of such procedures.

(e) *Glucose*.—In instances of "hypoglycemic shock" lack of glucose plays a specific rôle. Prevention of such a state consists in maintaining an adequate supply of glucose. Observation of patients with a high degree of hyperglycemia, whose sugar has been suddenly lowered to a normal level, suggests that this procedure may precipitate collapse.

(f) *Heat*.—Collapse and shock may be precipitated by loss of body heat, as in exposure to cold air or to cold water. Since the heat regulation is disturbed in all types of collapse and shock, it is important to prevent the loss of heat by applying warm blankets or by keeping the patient in a warm room. We have found that gastric irrigation with warm saline or warm bicarbonate solution is most effective in supplying the splanchnic area with heat. In instances of collapse associated with poisoning, such as in that due to morphine, the beneficial

response to gastric lavage instituted for the removal of the poison often depends on the stimulus to the splanchnic structures resulting from the heat supplied.

2. *Elimination of Abnormal Factors.* (a) *Sleeplessness and Fear.*—These factors play an important rôle in maintaining collapse. Induction of sleep with proper drugs is justified, but care must be taken not to use doses with depressant effect. This therapeutic problem has been discussed elsewhere.<sup>18</sup> Elimination of fear through reassurance is important in the treatment of both collapse and shock.

(b) *Pain* is a potent causative factor and it should be eliminated. Skill should be exercised in the selection of analgesics. Local counterirritants and analgesics may be helpful in reducing the dosage in the systemic administration of drugs which may have an undesirable depressant action on the vasomotor centers. Morphine should be used with judgment.

(c) *Toxins and Chemical Agents.*—Whenever collapse and shock are due to the action of chemical substances on the central nervous system or on the vascular wall, specific treatment is usually unsatisfactory. Many substances, such as bacterial toxins, immunological products, drugs and heavy metals, combine with structures of the vessel walls, and their elimination or detoxification cannot be accomplished effectively. Some of these substances, like histamine, epinephrine, acetylcholine and bacterial toxins, are rapidly "detoxified" when there is an efficient circulation: hence, if their source of entrance is eradicated, recovery rapidly follows. In this type of shock, therefore, therapy consists in treatment of the original disease (pneumonia, typhoid, burns, trauma, etc.) and in simultaneous maintenance of an efficient circulation, since even unstable substances are not "detoxified" if the circulation is in a state of collapse and shock. This we have had an opportunity to observe in patients who developed collapse and shock following surgical operation in which evipal was used as anesthetic. In shock due to heavy metals or other substances which form stable compounds with the components of the arterial, capillary and venous walls, the damage is often ir-

reversible and treatment of severe cases is frequently hopeless.

**Symptomatic Treatment.**—There are a number of measures which are useful in the treatment of collapse, regardless of its cause. In collapse and shock, as in syncope, the circulation is greatly influenced by gravity. The pooling of blood and, conversely, the return of blood to the heart, are greatly affected by changes in posture. We have demonstrated this in cases of collapse due to nitrite. Patients with collapse or shock should be kept in a horizontal position, or preferably in "*shock position*," with the head low and the body elevated. In acute collapse periodic elevation of the lower extremities is useful.

Dissipation of *heat* should be prevented by using warm blankets and by maintaining a high temperature in the sick room. If the patient has already suffered considerable heat loss and has a subnormal temperature when first observed, application of hot-water bottles alongside the body and the extremities is effective. Gastric and colonic irrigations with hot normal saline solution are also useful.

Further therapeutic measures should attempt: (1) to increase the circulating blood volume; (2) to reestablish the normal state of the central nervous system; and (3) to restore a balanced state of the vascular system.

Increase in the blood volume is usually most effectively accomplished by *blood transfusion*. As mentioned above, in cases of dehydration shock, infusion of saline or glucose solutions will be effective. In the majority of instances of shock, however, there is an increase in the permeability of the capillaries in one or more organs; hence crystalloid solutions rapidly leave the blood stream. For this reason, in such cases salt infusions can cause tissue edema in certain organs, while the blood and other organs remain in a state of dehydration. Intravenous infusion of *glucose* in the form of 100 cc of 50 per cent solution may temporarily elevate the osmotic pressure of the blood. Recently it has been claimed that sucrose leaves the blood stream more slowly than glucose; hence the osmotic

effects of sucrose are of considerably longer duration than those of glucose.<sup>19, 20</sup> Sucrose has been administered by slow intravenous injection in doses of from 50 to 200 cc. of a 50 per cent solution.

The use of 6 per cent *gum of acacia* in 20 per cent glucose and normal salt solution has been advocated. A volume of 300 cc. is infused at a rate of 5 cc. per minute. It remains to be established whether such a solution is without danger of late after-effects.

In instances of collapse where there is evidence of primary or secondary depression of the vasomotor center or reflexes, *strychnine*, *caffeine*, *coramine*, *cardiazol*, *ephedrine* and *benz-drine* are useful drugs. These substances increase the excitability of the vasomotor and other vegetative centers and reflexes. Strychnine, in addition to its effect on the vasomotor center and reflexes, increases the muscular tonus and activity. The latter effect aids the return of blood to the heart. The dose of strychnine varies with the condition of the patient. In collapse and shock associated with barbiturate poisoning we have administered subcutaneously or intravenously as high a dose as 10 mg. ( $\frac{1}{6}$  grain) at hourly intervals, and, as the patient's condition improved, have gradually reduced the dose to 2 mg. ( $\frac{1}{30}$  grain). We have found strychnine in doses of from 2 to 4 mg. ( $\frac{1}{30}$  to  $\frac{1}{15}$  grain), given at hourly or two-hour intervals, an effective remedy in acute collapse in infectious diseases and particularly in pneumonia. Caffeine sodium benzoate in doses of  $\frac{1}{2}$  to 1 Gm. (7 to 15 grains) intramuscularly or intravenously, coramine in doses of from 1 to 5 cc. of a 26 per cent solution injected slowly intravenously, and cardiazol in doses of from 1 to 5 cc. of a 10 per cent solution are particularly useful in acute collapse, such as develops during surgical operations, in infectious diseases and in cardiac disease. The improvement in the peripheral circulation observed following the administration of these drugs is secondary to an increase in the sensitivity and tonus of the vegetative centers. There is also a possibility that these drugs may exert a constricting effect on the venules

acting as blood depots, but there is not as yet adequate information to establish this point. Whether they can also influence capillary permeability through their central action is at present unknown.

Ephedrine ( $\alpha$ -hydroxy- $\beta$ -methylamino-propylbenzene) and benzedrine (benzyl-methylcarbinamine) are particularly useful in the prevention and treatment of collapse and shock associated with unconsciousness and coma, such as occur in poisoning due to hypnotics and anesthetics. Whether they exert a similar useful effect in other types of collapse has still to be established. These substances stimulate several centers, particularly those regulating consciousness. We have administered to patients with severe barbiturate poisoning 30 mg. ( $\frac{1}{2}$  grain) of ephedrine or 15 mg. ( $\frac{1}{4}$  grain) of benzedrine intravenously or intramuscularly at intervals of two hours. With clinical improvement the dosage should be reduced and the interval prolonged.

There is at present but scant pertinent information on the rational use of substances acting directly on the peripheral vessels. We know that in the majority of instances of collapse and shock there coexist arteriolar constriction and dilatation of the capillaries and venules. In another group, however, there is arteriolar as well as venous dilatation. It is also probable that these two types of vascular abnormality occur simultaneously in various organs in the same patient. The coexistence of such different vascular states offers an explanation for the difficulty encountered in attempting any routine treatment of shock.

A chemical substance which exerts a constricting effect solely on the venules will be of particular benefit in the treatment of collapse and shock, whereas a substance which simultaneously induces constriction of the arterioles as well may further impair the blood supply to the tissues. For this reason the indications for the use of epinephrine in collapse and shock are not entirely clear. In transient peripheral circulatory collapse, just as in syncope, especially where arterial and arteriolar dilatation predominate, the subcutaneous administration

of 0.5 to 1 mg. ( $\frac{1}{120}$  to  $\frac{1}{60}$  grain) will promptly elevate the arterial blood pressure and improve the venous return of blood to the heart. Similar doses will be effective also in collapse due to acute cardiac inhibition or to other types of bradycardia. In shock or in prolonged collapse, its use may be followed by temporary improvement but subsequently the circulatory failure frequently becomes accentuated, and a repeated dose may be harmful. There is evidence, on the other hand, indicating that the continuous infusion of an epinephrine solution of low concentration, which will constrict the venules but will not produce spasm of the arterioles, may be beneficial. *The effect of epinephrine on various types of vessels and on the heart depends, therefore, on the concentration of epinephrine in the blood.* For therapeutic purposes this concentration can best be controlled by intravenous infusions. In collapse a solution of 1:100,000 (1 cc. equals 0.01 mg.) infused at a rate of from 0.25 to 5 cc. per minute may be beneficial, and such a rate can be maintained for hours or even for days. Whether the effect of epinephrine may be different in certain types of advanced collapse because of the abnormal state of the arterioles, capillaries and venules, we do not know.

Synephrine (p-oxyphenyl-ethanol-methylamine hydrochloride), which has an effect similar in many respects to that of epinephrine, is also useful in acute collapse such as occurs after strenuous work, in the course of infectious diseases and during surgical manipulations. It has a more prolonged effect than epinephrine, but, on the other hand, it is a less effective vasoconstrictor. Our present knowledge does not justify its use in shock. In collapse a solution of 1:1000 at a rate of from 1 to 5 cc. (1 to 5 mg.) per minute may be given intravenously for one to two hours several times daily. It may be given orally and rectally in solutions of 100 mg. per liter.

The administration of pituitrin or of pitressin, the pressor fraction of pituitrin, in collapse and shock, is not justified in the light of present knowledge. In experimental animals and in man pitressin produces a lowered basal metabolism, markedly decreased cardiac output, decreased peripheral flow,

and lowered pulse rate.<sup>21</sup> Such circulatory effects do not furnish a rational basis for its use in collapse and shock. Nevertheless, it has been advocated in certain types of acute circulatory failure by those who have tried it clinically. Thus Wenckebach and Aalsmeer have found it benefit in the collapse and shock of "wet" beriberi.<sup>22</sup>

## VII. SUMMARY

Syncope, collapse and shock are syndromes of the acute noncongestive ("anoxic," "forward") type of failure of the circulation. The essential difference in the bodily changes occurring in each of these syndromes is quantitative rather than qualitative. For this reason a sharp clinical differentiation between them may in certain patients be difficult. The duration as well as the severity of the circulatory disturbances plays a decisive rôle in determining their prognostic significance. If the circulatory failure is prolonged, the secondary tissue changes due to anoxia become less easily reversible and finally irreversible. Syncope, collapse and shock frequently occur not only in their "pure" noncongestive form, but also in combination with the congestive type of circulatory failure. Rational treatment requires a knowledge of the specific mechanism underlying each of these syndromes, as well as an understanding of the nature of the secondary disturbances present. Both specific and symptomatic measures useful in the treatment of syncope, collapse and shock are presented.

## CLINIC OF DR. ROBERT T. PHILLIPS

ROBERT B. BRIGHAM HOSPITAL

### PRACTICAL MEASURES FOR THE MANAGEMENT OF CHRONIC ARTHRITIS IN THE HOME

Two million Americans, it may be conservatively estimated, are afflicted with acute and chronic arthritis. Not more than 15 per cent of this number, in all probability, are under medical supervision. The failure of the medical profession to find a specific therapy for chronic arthritis has led to a very general belief among laymen and even among physicians that very little can be done about it. Consequently, beneficial claims are made for a wide variety of drugs advertized in every newspaper and magazine. The suffering patient vainly turns from one treatment to another, follows the advice of family and friends, and finally is resigned to the prospect of partial or complete invalidism. The challenge to the medical profession which we constantly face from chronic arthritis and rheumatism has been accepted only in the last few years. More work has been done since 1926 to enlighten us on the problem than in all previous history. During the past ten years, it has become evident that while no specific therapy of proved value has been developed, many forms of treatment are available to us which, taken together, offer in the light of our present knowledge the best possible means of controlling this disorder.

There is no short cut in the treatment of rheumatism. For ten years now the American Committee for the Control of Rheumatism has been preaching the doctrine of a wide angle attack, with emphasis on efforts to restore, insofar as may be possible, the patient's general constitutional equipment to a functional level. This approach necessitates a careful

scrutiny of the individual's physiological activity in each of the separate systems, with a view to encouraging better function in those where deficiencies exist.

Few hospital staffs are adequately trained to care for the arthritic. Until the profession itself is awake to its responsibility, an aroused public opinion cannot be expected to face this scourge as it has faced the problems of tuberculosis and cancer. Sanatoria for arthritis may come in the future, but for the present, the pertinent question is what to do for the arthritic who must remain in his home.

After a careful appraisal has been made of the patient's constitutional state, and the various functional deficiencies noted, a program should be established for him to follow out at home. In order to visualize the possibilities in establishing such a daily routine for a patient, I have tabulated the elements of treatment in the accompanying tabulation. The remainder of this paper will be a consideration in some detail of practical methods of therapy under the following headings:

- |                              |                          |
|------------------------------|--------------------------|
| 1. Rest and exercise.        | 5. Vaccines.             |
| 2. Special physical therapy. | 6. Occupational therapy. |
| 3. Orthopedic aids.          | 7. Drugs.                |
| 4. Diet.                     | 8. Psychotherapy         |

**1. Rest and Exercise.**—Rest is the first and most important method of treatment in arthritis; rest for the affected joints locally, and rest very often for the body as a whole. When confined to bed, the patient should not be allowed to occupy for indefinite periods the position most comfortable for him to assume. He should be instructed to practice postural exercises three times daily after meals. The bed should have a firm, nonsagging mattress. The pillow being removed the patient first lies in the hyperextension or horizontal position, the hands placed behind the head or neck to help raise the ribs and flatten the dorsal spine. A small pillow may be placed under the chest, and in the beginning several small pillows may be used to support the knees, these pillows being removed as the hyperextension positions can be taken without too much discomfort.

## OUTLINE OF THERAPY FOR THE MANAGEMENT OF CHRONIC ARTHRITIS IN THE HOME

## 1. Rest and Exercise:

Bed exercises.  
Breathing exercises.  
Sitting exercises.  
Standing exercises.  
Posture training.  
Muscle training.  
Overhead frame.

## 2. Physical Therapy:

Fomentations.  
Paraffin.  
Baths.  
Massage.  
Baker.  
Foot soaks.  
Hot-water bottle.  
Electric pad.

## 3. Orthopedic Aids:

Flannel bandages.  
Elastic bandages.  
Adhesive strapping.  
Thomas collar.  
Plaster splints.  
Corset, brace.  
Foot plates.  
Arch cuffs.  
Calipers, crutches.

## 4. Diet

Fresh fruits  
Fresh vegetables  
Cod liver oil  
Low carbohydrates  
Feeding between meals  
Salts and orange juice  
Hot abdominal packs  
Isulin  
M.M.  
Weight reduction

## 5. Vaccines:

Subcutaneous.  
Intramuscular.  
Intravenous.  
Autogenous.  
Typhoid.  
Foreign protein.  
Dosage.  
Frequency.

## 6. Occupational Therapy:

Knitting.  
Painting.  
Weaving.  
Woodworking.  
Modeling.  
Rug making.  
Carpentry.  
Games.  
Hobbies.

## 7. Drugs:

Salicylates.  
Arsenic.  
Potassium iodide.  
Iron.  
Sulfur.  
Cinchophen.  
Thyroid.  
Follicular hormones.  
Opiates.

## 8. Psychotherapy:

Optimism.  
Encouragement.  
Confidence.  
Supervision.  
Patience.  
Sterile hypos.  
Placebos.

After thirty minutes, the "face prone position" is assumed for a similar period. In this instance the patient is instructed

Fig. 31.—Hyperextension position with the body in a horizontal position with pillow under the knees and chest. The arms are extended over the head to help raise the ribs and flatten the dorsal spine. Note how the thorax is raised to the position of full inspiration encouraging free excursion of the diaphragm.

to lie on a pillow placed lengthwise under the chest and abdomen. The purpose of these positions, which are described

Fig. 32.—"Face prone" position. The patient is lying prone with pillows under the abdomen and pelvis. Note the flatness of the back and the fullness of the chest.

in the book "Body Mechanics,"<sup>1</sup> together with other exercises for posture training, is to counteract gravitational effects which

increase the sag of the organs and the strain on the body as a whole. These two positions represent the nearest approach we have to complete physiological relaxation. The elevation of the diaphragm encourages the development of better circulation and muscle tone in that organ while at the same time a more active circulation is permitted through the vascular channels of the abdominal cavity and the structures contained within it. Respiratory movements increase in range, developing a greater vital capacity.

Muscle training exercises are easily done whether or not the patient is confined to bed. For an outline of measures useful in developing muscle control and improved posture, the reader is referred to the above-mentioned book. My primary purpose in touching on this subject is to suggest the opportunities for educating the patient through daily practice to get his body into better condition to cope with his arthritis. For bed patients a simple overhead frame may be erected. A bar for the hands and elastic loops for the legs will provide the means for additional exercise not possible otherwise. Rest for the joints locally will be considered under orthopedic aids. It should be borne in mind that constitutional rest is invariably beneficial to the local manifestations.

**2. Special Physical Therapy.**—Heat in its various forms remains the chief agent of physical therapy for the arthritic patient. I do not believe that the more elaborate forms of electrotherapy have much, if anything, to offer that is superior to the old-fashioned hot fomentations or the dry heat from an inexpensive electric light baker. Details for making a home-made baker may be found in a small pamphlet entitled, "Useful Therapeutic Measures," published by the Council on Physical Therapy of the American Medical Association. Fomentations are best given by wringing out a woolen cloth which has been soaked in hot water, after which the cloth is wrapped about the part to be treated and covered with a heavier dry towel which serves to prevent the heat from escaping too rapidly. This procedure may be safely carried out once a day in most patients and twice daily if the patient has no temperature,

circulatory insufficiency, or other constitutional disturbance.

Massage may follow the application of heat with benefit. It should be remembered, however, that the application of massage should never add by trauma to the inflammation which may be present already in an affected joint. Hence, massage should be practiced in the neighborhood of, but not immediately over, the involved joint. The strokes should be in the direction of the venous flow. Fifteen or 20 strokes to the minute for a period of one-quarter hour will suffice for the usual treatment. The involved limb should be moved by the patient himself through as great a range of motion as is possible without pain twice daily. Passive motion within the painless range at the time massage is done will encourage the patient in this regard. Active motion, that performed by the patient unassisted, is to be encouraged. He must be taught to do what he can for himself, within the limits of his physical resources.

Melted paraffin is an excellent way to apply heat to arthritic joints, and this method may readily be carried out in the home. No equipment is required other than a 5-quart container or double boiler, 8 pounds of wax, obtainable at any filling station, and a burner. The wax melts at a temperature of 120° F., and the patient will be able to dip his hands safely in the wax when it starts to solidify over the top. Five or 6 coats will give the patient a pair of warm gloves which are then wrapped in a towel until the heat is dissipated. The wax may be painted in layers over larger joints. One treatment daily will be sufficient.

Warm baths at home should be employed for their mildly stimulating effects upon the circulation, as well as for their sedative properties. Under-water massage for those who may take tub baths should not be overlooked by reason of its marked sedative influence. Foot soaks are available in any household, and where swelling or edema is present, magnesium sulphate may be added to the water, 1 ounce to the gallon. The hot water bottle and the electric heating pad are also readily available sources of heat, and will do, in my opinion,

quite as well as more expensive and time-consuming measures as, for example, iontophoresis.

**3. Orthopedic Aids.**—The more fundamental orthopedic aids to the treatment of arthritis can be carried out almost as well in the patient's home as in a hospital. Our point of view in this regard is directed toward the protection of joints and the prevention of deformity. Flannel and elastic bandages are readily available and should be used more often than they are. An acutely inflamed joint should be well wrapped to give support to the joint structures, thus favoring subsidence of the inflammation. For elbow or knee, the preliminary application of liberal amounts of sheet wadding followed by flannel and elastic bandages usually effects a prompt reduction in acute processes. Adhesive strapping may be applied in criss-cross fashion to fingers, wrists, elbows, shoulders, knees, and ankles with good effect when swelling is present.

It is an error to presume that an arthritic joint will tend to stiffen unless motion is kept up at all costs. The fallacy of this notion, which was formerly widely preached by the medical profession, has been clearly demonstrated by Goldthwait, Swaim, and their associates at the Robert B. Brigham Hospital. For a dozen years patients at this institution have been provided with light plaster splints molded to the individual joint where inflammation was present. In no instance has this form of therapy led to ankylosis. While the application of plaster in the home may be attended with certain difficulties, it is entirely possible to provide home patients with short plaster arm supports in those cases where the wrists and fingers are involved. Such a "shell" can be quickly made in the following manner. Cut a piece of  $\frac{1}{4}$ -inch felt, 5 inches in width, extending from just below the bend of the elbow to just beyond the fingertips. Along one side, cut an indentation for the thumb. Two rolls of plaster are turned back and forth over the felt. The wet splint is then applied to the forearm and hand, felt side to the skin, a gauze bandage holding it in place. While it is hardening, the hand, wrist, and fingers are held in the position desired, usually with the wrist in extension

Fig. 33.—Three types of plaster hand "shells," each made with one roll of plaster. They can be made in a very few minutes at the bedside and molded to support the joints in the desired position.

Fig. 34.—Types of leg "shells." *Above:* Short foot boot, useful for protecting the ankle and maintaining good position of the foot. *Center:* Long leg "shell" employed for relaxing the knee joint and correcting flexion deformity. Note the extension on the toe to carry the weight of the bed clothes. *Below:* Posterior walking slab.

and the fingers in midflexion. After drying, the splint is trimmed with adhesive tape. Such an appliance will effectively immobilize tender, actively inflamed joints, preventing subluxation of the carpal joints and ulnar deviation of the fingers. The splint should be worn day and night for the first week, being removed for fomentations, wax, massage and exercise. In like manner plaster "shells" may be fitted to the lower extremities. Outward rotation of the tibia and foot can usually be prevented in this manner. The plaster splints can be very effective in supporting the joints in their best positions favoring normal function. By changing the "shells" once a week, early contractures can usually be corrected.

When a patient is getting up after prolonged bed treatment, posterior walking slabs may be made in the same manner. These will be fitted from the mid thigh to just below the calf, and will be bound on with flannel bandages. In this manner the joints will be supported in weight bearing, while at the same time the additional strain of motion will be avoided.

Medical men should get over their unwillingness to handle plaster, particularly with respect to its use in arthritis. Some of the medical supply houses are now putting up plaster bandages in neat, convenient packages, which renders the material available to all, in a form ready for instant use. The use of plaster as here advocated does not imply that it is time-consuming or that special training is necessarily required. A conscientious physician will find the few extra minutes it takes well worth while in results achieved. The more extensive use of plaster as, for example, the complete extremity cast, body jacket, or spica, are of course scarcely possible to manage in the home.

The patient with neck symptoms will be grateful for a Thomas collar, which can be made at his home in a few minutes. A piece of cardboard is cut approximately 4 inches in width, curved high to fit just under the ears and cut out below to fit over the trapezius muscles. It is also cut to dip down in front to accommodate the distance between the clavicles and the mandible. The collar fastens in back of the neck

Fig. 33.—Three types of plaster hand "shells," each made with one roll of plaster. They can be made in a very few minutes at the bedside and molded to support the joints in the desired position.

Fig. 34.—Types of leg "shells." Above: Short foot boot, useful for protecting the ankle and maintaining good position of the foot. Center: Long leg "shell" employed for relaxing the knee joint and correcting flexion deformity. Note the extension on the toe to carry the weight of the bed clothes. Below: Posterior walking slab.

and the fingers in midflexion. After drying, the splint is trimmed with adhesive tape. Such an appliance will effectively immobilize tender, actively inflamed joints, preventing subluxation of the carpal joints and ulnar deviation of the fingers. The splint should be worn day and night for the first week, being removed for fomentations, wax, massage and exercise. In like manner plaster "shells" may be fitted to the lower extremities. Outward rotation of the tibia and foot can usually be prevented in this manner. The plaster splints can be very effective in supporting the joints in their best positions favoring normal function. By changing the "shells" once a week, early contractures can usually be corrected.

When a patient is getting up after prolonged bed treatment, posterior walking slabs may be made in the same manner. These will be fitted from the midthigh to just below the calf, and will be bound on with flannel bandages. In this manner the joints will be supported in weight bearing, while at the same time the additional strain of motion will be avoided.

Medical men should get over their unwillingness to handle plaster, particularly with respect to its use in arthritis. Some of the medical supply houses are now putting up plaster bandages in neat, convenient packages, which renders the material available to all, in a form ready for instant use. The use of plaster as here advocated does not imply that it is time-consuming or that special training is necessarily required. A conscientious physician will find the few extra minutes it takes well worth while in results achieved. The more extensive use of plaster as, for example, the complete extremity cast, body jacket, or spica, are of course scarcely possible to manage in the home.

The patient with neck symptoms will be grateful for a Thomas collar, which can be made at his home in a few minutes. A piece of cardboard is cut approximately 4 inches in width, curved high to fit just under the ears and cut out below to fit over the trapezius muscles. It is also cut to dip down in front to accommodate the distance between the clavicles and the mandible. The collar fastens in back of the neck

with a buckle or gauze tie, and thus the weight of the head is taken in part directly upon the shoulders, relieving the strain on the cervical spine.

Such accessory apparatus as a well-fitted back lace corset for women, an abdominal belt for men, steel back brace, foot plates, calipers, and crutches, may be provided in the home, but for such equipment it will be best to confer with an orthopedic consultant. The majority of deformities attributable to arthritis are preventable, but good results will not follow sketchy therapy. These orthopedic aids are of prime importance, and should be used to full advantage as early in the course of the disease as possible.

**4. Diet.**—There is no one type of diet applicable to all patients with chronic arthritis. In general a dietary high in vitamin-containing foods, moderate in caloric value, with liberal quantities of fresh fruits and vegetables is most suitable. In my opinion a restriction in carbohydrate intake is indicated. Pemberton has produced considerable evidence suggesting that the arthritic does not utilize sugars and starches to best advantage. Moreover, the gastro-intestinal tract itself, usually functioning subnormally in these patients, should not be subjected to the extra burden of an excessive carbohydrate intake. The digestive apparatus should be considered as one of the important systems which must be adjusted to its optimum functional level in our efforts to restore the patient's "physiological equilibrium." For diet lists, with a critical discussion of the entire subject, the reader is referred to Pemberton's book.<sup>2</sup>

Constipation as a concomitant symptom is almost the rule in arthritis. The practice of occasionally placing these patients on a twenty-four-hour diet of orange juice and magnesium sulphate brings with it prompt alleviation of symptoms. This may be done by giving the patient 1 ounce of magnesium sulphate in a glass of hot water flavored with lemon juice on rising. A glass of milk is provided in place of the three daily meals. One tablespoonful of mineral oil with 1 teaspoonful of the fluid extract of cascara may be given once or twice daily

to regulate the bowels, the cascara being quickly cut down or withdrawn within a few days. The use of hot wet abdominal packs after meals will help in promoting better absorption, and this procedure, in conjunction with 5 units of insulin before meals, may bring about a gain in weight in undernourished individuals with poor appetite. The insulin may be increased 5 units a day until 20 units are given before each meal.

The feeding of extra calories between meals in the form of milk shakes or egg-nogs has benefited many. Vitamins have been advocated in various forms. Responsible workers in the field have urged the use of vitamin B in arthritis, others have emphasized the value of vitamin C, and still others, with equal authority, have urged that vitamin D be administered in large quantities. Cod liver oil appears to retain its original merit, and is favored by most investigators, either in liquid or tablet form, over the numerous proprietary vitamin products on the market. It should be taken regularly by arthritics, especially during the winter months. Milk, containing as it does all of the vitamins, may be included with profit in the dietary of every patient.

Weight-reducing diets are of the first importance in the treatment of osteo-arthritis, where the weight-bearing joints are implicated. A sharp loss in weight may be the only effective means of securing definite relief from symptoms.

5. **Vaccines.**—In the home treatment of chronic arthritis, it is quite possible to carry on a course of vaccine therapy, injections being given once a week. If the attending physician will consider the vaccine an adjunct to the program which he has instituted, I would favor the use of vaccines in selected cases. It should be avoided in acute forms of the disease, unless very small doses are used. The lack of uniformity in dosage, organism selected, as well as method of application, that is, subcutaneously, intramuscularly, or intravenously, suggests that investigators have not yet found a common ground on which to meet as far as vaccine therapy is concerned with arthritis. Recent work by Dawson lends additional support to the theory of a streptococcal factor which may yet prove an

important element in the etiology of the disease, but until more conclusive evidence is at hand, we should not allow ourselves to be carried away with the idea that any form of vaccine therapy is of genuine merit. I personally favor small doses of a mixed streptococcus vaccine by the intravenous route, starting with 50,000 to 100,000 organisms, always endeavoring to keep below a reaction dose.

Foreign proteins are of extremely limited value in chronic arthritis. In gonorrheal arthritis they may occasionally be useful by reason of the increased temperature produced. For this purpose typhoid vaccine appears to be as effective as any, starting with 25,000,000 organisms intravenously, increasing by a like amount at intervals of four days, within the limits of the patient's tolerance.

**6. Occupational Therapy.**—It does not follow that enforced rest means enforced idleness. The arthritic patient should be encouraged to engage in some form of productive work which will serve the double purpose of providing mental stimulation and exercise for the affected joint. If the patient can produce some bit of work, however trivial, he will have the incentive to go on to further achievement. Knitting, painting, woodwork, modeling, braiding, making hooked rugs, dominoes, cards, and other games may be the means of restoring self-confidence and promoting greater independence.

**7. Drugs.**—Most of the common drugs and many of the unusual ones have been advocated for the treatment of arthritis. Patent medicines have thrived and are thriving today on an unsuspecting arthritic public. Very few drugs have stood the test of time. The salicylates, arsenic, potassium iodide, and iron have a definite place in the drug therapy of arthritis. The salicylates should not be employed for indefinite periods, indeed, it is usually possible to decrease dosage rapidly, omitting the drug entirely as the patient approached a more stable functional balance. To depend on salicylates as a primary agent in controlling the disease is to court disaster. Arsenic in small quantities is useful as a tonic and tissue stimulant in those individuals debilitated through long standing illness. It

may be given in the form of Fowler's solution in gradually increasing amounts, in the form of sodium cacodylate  $\frac{1}{12}$  to  $\frac{1}{4}$  grain three times a day, or intravenously, as it is used in antiluetic therapy. In the latter case, a vacation should be permitted after 6 injections. Potassium iodide, 5 drops in water three times daily, increasing to 10, often exerts a favorable influence on metabolism. Iron is frequently essential in controlling the secondary anemias so common in arthritis. Feosol is a suitable preparation for this purpose.

Opiates should never be used, except in emergencies. Suspect malignancy in the patient with arthritis whose pain requires the prolonged administration of opiates.

Cinchophen has no special merit in chronic arthritis.

Very recently hormone preparations have been used with some success, and it is likely that this field offers more for the future. An example in point is the use of the follicular ovarian hormone hypodermically for the relief of symptoms associated with menopausal arthritis or "arthralgia," particularly when vasomotor disturbances and menstrual irregularities are present. Thyroid substance in small doses may be used with discretion, more especially in osteo-arthritis, where it is thought to be most effective.

The best to be said concerning a host of other drugs is that occasionally someone appears to derive benefit for reasons which cannot be explained. Students of the subject agree in general that the place of drug therapy in arthritis is exceedingly limited, and any treatment of this nature cannot hope to compensate for the absence of a fundamental program upon which all forms of special treatment should rest.

§ **Psychotherapy.**—Worry, anxiety, fear, and other emotional states exert a deleterious influence upon the course of chronic arthritis. The patient's family and friends can help materially by cultivating his self-confidence and turning his thoughts to those things which point to progress and returning health. The clergy may do much in this regard, and their services should be sought as occasion demands.

I cannot emphasize too strongly the important share that

a spirit of continued optimism and friendly encouragement on the part of the physician may take in effecting satisfactory progress on the part of the patient. Too many patients have been disappointed and chagrined to discover that the doctor who would take a genuine personal interest in their arthritis was not to be found. Haphazard guess work in one direction or another inevitably leads to disappointment all around.

The physician who proceeds along the outlines suggested in this paper will find himself able to talk with his patients with confidence and assurance based upon results that cannot be discounted.

## CLINIC OF DR. BRONSON CROTHERS

### THE CHILDREN'S HOSPITAL

---

#### THE PRACTITIONER'S RESPONSIBILITY TOWARD THE NERVOUS CHILD

MENTAL hygiene, with or without capitals and quotation marks, has been discussed inside and outside of the medical profession for about twenty-five years. During the same period extramural psychiatrists have gained a valid place for themselves as indispensable practitioners in large communities. Psychiatric social service workers, psychologists, visiting teachers, visiting nurses and, more recently, various official groups under government auspices, are dealing with many problems which, if handled at all, used to be regarded as responsibilities of doctors in general.

Those physicians who deal with children, whether as pediatricians or as general practitioners, have taken a very small part in the discussions. Yet one of the major aims of the most vigorous of the various groups has been the prevention of mental disease by judicious management of children and of the teachers and parents who control them.

The slogan "mental disease is preventable, mental health is procurable" happens to be the one that recurrently faces doctors in this community who open their mail conscientiously. If this is true, it is evidently the duty of doctors at large to make a sincere effort to understand and to cooperate. Otherwise they will be forced to share the sense of guilt which oppresses those who should have foreseen and averted disaster. If the slogan is not correct they are in a position to comfort many distressed parents whose children have not achieved satisfaction when they began to compete in the world.

A very complicated and serious situation exists when the practitioner is asked to advise parents whose children's behavior is not satisfactory. The fact is evident enough that the ordinary methods of medical practice are almost irrelevant. The doctor is tempted to apply the definitive, episodic observations which are so useful in ordinary practice, to the problem of behavior. He is then in the rather absurd position of advising about treatment when he has no direct knowledge of the condition he is discussing. This situation strikes me as an extremely important one, particularly if we intend to try to "prevent mental disease." At the risk of repeating perfectly obvious platitudes a few remarks seem in order about medicine in general.

In ordinary medical practice among adults the history is obtained by a series of questions and answers. Some of the primary ones are aimed at the establishment of a date on which the patient was in normal health. This basic point is set at a time when the individual was at work without distress, was at a proper weight and enjoyed himself at meals and at play. The assumption is made that this evidence justifies the statement that the individual was a well-standardized product. The disease then occurred and the patient departed from his normal state of health and fell into a state of illness. The nature of the deficit in weight, in comfort, in motor ability and in mental efficiency is then inquired into, and the physician proceeds to investigate the physical status and perhaps calls upon a laboratory to investigate phases which elude the eyes, the ears and the fingers.

In children the situation is modified, of course, by the fact that steady growth is going on. It is therefore less easy to establish a base line, but since most of the diseases of children are acute, the difficulty is not too great. One of the major difficulties is evident enough in prolonged illness. Recovery in an adult is restoration to a previously achieved level. If an adult is as "good as ever" the doctor agrees that all is well. If, however, a child has been ill and at the end of six months is where he was to start with, he is suffering from "ar-

rest of development." Evidence of restoration to a proper rate of growth and development is obviously one of the things that we need before we dismiss a child after serious illness.

The problem which faces anyone who tries to deal wisely with children whose behavior is unsatisfactory cannot be dealt with by the medical routine unless the doctor is willing to shift his emphasis to a very considerable extent. It seems quite clear that the history must be taken in a very different way and that the physical study is likely to take a secondary part. The precise methods of the laboratory are likely to be even less important. Moreover the physiological study of the physical machine is less apt to reveal significant clues than a study of the behavior of the child.

It is at this point that the practitioners of organic medicine and the psychiatrists are likely to arrive at an impasse. The psychiatrist is very rarely faced by the problems of fever, pain or malnutrition, which make up the bulk of the presenting symptoms in pediatrics. Most of his patients are physically in fair condition. As a result the psychiatrist can afford to spend time in almost unlimited measure in interviewing parents or observing children, while the general practitioner or the pediatrician is accustomed to reach a conclusion at once. This sense of time has, I think, more importance than most of us realize. The statement, which is so frequently made, that the general practitioner has "not time," has been regarded with impatience or incredulity by the propagandist who advises doctors in general to deal with problems of behavior.

At this hospital we have been trying to find out whether we can work effectively with behavior problems within the time limit which is acceptable in pediatric practice. Furthermore, we have been exploring the possibility of appraising emotional and intellectual difficulties which occur in sick children before they can be released from medical supervision. At present we are dealing, in large measure, with children whose difficulties of behavior seem too confusing to be soluble in the general medical out-patient department or with those whose physical status demands ward care.

We have arranged the time of interns and of the rest of the staff so that it is possible to take histories at leisure. Furthermore, the senior members of the staff regard the history with interest and frequently cooperate in collecting it. The questions relating to growth and development are carefully considered and the mental status is considered by the psychologist who works in the ward. In addition to a careful psychological study of the child, she interviews the parents and collects relevant information about the developmental history and the educational status.

Every pediatrician knows only too well that it is difficult to appraise emphasis in histories or even to elicit facts from an anxious mother who is distressed by the behavior of a child. Too often the physician makes a guess and decides to proceed on the theory that the child is being mismanaged. A large number of well-informed and conscientious women are all prepared to accept this decision and are eager to apply remedies. Of course, there are plenty of situations where experienced doctors can help oversolicitous mothers by routine advice. On the other hand we, at this hospital, have serious doubts concerning the validity of the sort of advice which is frequently given if it is not preceded by adequate observation.

In many cases it seems wise to insist on a chance to observe the child before laying down the law. Fortunately we have a corner of the hospital at our disposal where we can watch children in action. Beds do not fill all the space. There is room for play and for teachers, so that relevant observation is possible. In addition we have medical and psychological supervision, but the essential point for the purpose of this clinic is that the behavior of children is subject to observation. The amount of space available here is liberal because we happened to be lucky in formulating plans just at the moment when generous supporters were ready and able to help us. Without this support we would have had to find space as we could. However, it is not essential to duplicate this plant before starting the investigation of behavior as an element in the study of medical cases. The fitting of a new enterprise into hospital

space is largely solved when trustees and staff agree that effectiveness of service can be increased by providing the new service.

The essential shift is one of medical emphasis. The decision to accept behavior of children as a phenomenon to be studied in a hospital means that psychological investigation must be provided for, that contact with teachers must be arranged and that time and space must be sought. It is not easy to make adequate adjustments, but without such adjustments there is not much use in starting. Frequently it is entirely reasonable to seek cooperation with existing agencies, so that a fully equipped staff is not needed.

Obviously the experienced practitioner, after watching a competent unit, gains the same type of competence in choosing cases which should be referred to psychiatrists that he acquires by watching skilful surgeons or other specialists in a highly organized environment.

The general method used in the ward can be easily described by showing cases.

Case I.—A Jewish girl of six and one-half years was brought to the hospital after being excluded from school for tantrums and impertinence. The exclusion from school was not the result of an impulsive act on the part of an angry teacher, but was forced by a succession of overt acts which upset school routine and the procedure was advised by a highly competent visitor. The mother struck us all as a very difficult, harassed woman who was trying to fight her way out of an almost impossible situation. It seemed unlikely that we would be able to accomplish much unless we did two things. First, it seemed essential to remove the child from home and second to investigate the behavior of the child ourselves. After some backing and filling, we succeeded in having the child admitted. The general attitude of the mother was that the child was an attractive, lovable little thing whose acquaintances sought her companionship. She admitted under pressure that she was capricious in her eating, slept poorly and did not behave well in school. Clearly, she wished to give the impression that she blamed the school and she expected us to support her.

The physical study was essentially negative except for strabismus. The ordinary psychometric studies confirmed those done in school which indicated that the intelligence level was above the average. She had no intellectual peculiarities which would explain resistance or unhappiness at school. The few days in the hospital were interesting from several points of view. First, the child although she sought attention and responded to it, was not at all unmanageable. She conversed freely and it was on the basis of her conversa-

tion that we were able to discuss previous management with the mother. It required some care to avoid breaking faith and at the same time to use all relevant material, but before we got through it was possible to be entirely frank all around. Second, the mother lost most of her combative attitude and was able to discuss her management and to argue about changing her methods. Third, through cooperation with school system it was possible to avoid a situation where a teacher was forced to readmit a child she had dismissed. These arrangements were made, not by us, at the hospital, but by school authorities.

In this case we were, of course, using rather formidable machinery and were cooperating with a large school system. The success of the effort, which we have followed for many months, is due, I believe, to a type of cooperation between doctors, teachers and psychologists, which can be used over and over. The school and the home had clashed. A child, perfectly capable of orderly school progress, had been removed from school. As so often happens the medical profession was called upon to intervene, not because doctors, as such, are particularly informed upon the matters at issue, but because the traditional prestige of medicine was valuable. The main reason our intervention worked well was, I think, that we were given an opportunity to observe the child during a period when parental wrath was cooling off.

Case II.—A cheerful little girl of two years and eight months was brought to the hospital because the mother was troubled by persistent head banging at night. She sucked her fingers, she had to be urged before she would eat a diet which satisfied her mother. Even under the rather difficult conditions of the out-patient clinic the child was extremely active and both the young and active parents were watching her and were all set to start after her whenever she began to move. The upshot of a reasonably leisurely interview was the rather obvious conclusion that the child was physically adequate, extremely restless and not feeble-minded. We had, of course, no direct evidence whatever as to the head-banging episodes or other things that were reported. The question arose at once as to the advisability of admission of such a child for study. The parents seemed to be in a good physical state and, though rather anxious, did not seem exhausted. Obviously they were overstating the case when they said they had hardly slept at all for months. It was a temptation to impress them with the fact that they were oversolicitous about a healthy child, give them a fight talk about judicious neglect and a suitable routine and pass on to the next case. Another possibility was to acknowledge the need of study, but to call upon a psychiatric unit to conduct it.

The quick, rather unpredictable activity of the child suggested the un-

inhibited behavior of children after cerebral injury or encephalitis. We have frequently seen management fail in such cases, and mothers battered in the process. In order to lay a foundation for advice the child was admitted. The physical study revealed no evidence of organic disease. The psychologist was not able to conduct an orderly test at one sitting on account of the restlessness of the child, but had enough evidence to suggest a developmental status between two and two and one-half years. The nurse's notes, the nursery school teacher's notes and the repeated episodic observation of the rest of the staff impressed us with the essential accuracy of the general story by the mother. It happened that the things we saw were not identical with those reported. For instance, head banging at night was not noted, but the child did a lot of rocking in chairs and on playthings and showed her passion for repetitive rhythmic activity. No conventional masturbation was observed. She was persistently restless and overactive and no routine modified the situation. Careful consideration of the home routine convinced us that no change in management would transform the picture.

At the end of a few days we were able to talk intelligently with a mother who was rested enough to discuss matters calmly and go over the very difficult problem that faced her. We were able to reassure her about her own competence and the whole situation, though still very difficult, was handled with reasonable security on both sides. At the very least we avoided the frustration which must have ensued if we had impressed her with the entirely unjustified idea that she could modify management and obtain an orderly and docile child in short order. At subsequent visits we were able to deal with the recurrent problems with confidence since we had the background obtained by direct observation. To some extent it is now possible to discuss with the mother and father shifts of procedure and attitude which might be tried. All of us, I think, are quite convinced that a few days' observation saved many hours of rather confused and unsatisfactory speculation in the out-patient department.

**Case III.**—A girl of seventeen months was brought to the out-patient department with a story of convulsive attacks at long intervals since she was ten months old. The history suggested that her development was a bit retarded and she was decidedly small for her age. Without direct observation the diagnosis of epilepsy in an undernourished and perhaps feeble-minded child had something in its favor. Certainly the initial story suggested some such situation.

On admission we discussed the problem at leisure and found that the mother had worried about management all the time. Food habits, discipline and inadequate behavior were worrying her, entirely aside from the startling episodes of crying, cyanosis and weakness which had been interpreted as convulsive attacks.

The child spent a month in the hospital. The strictly structural study revealed a few evidence of interference with growth, presumably due to nutritional disturbances, which were described by the mother. Otherwise nothing of importance was found. The regulation of her food habits by allowing her to eat her favored but suitable diet was successful from the start. We used the method which Dr. Clara Davis has so adequately proved at the Memorial

Hospital in Chicago. The summary of the nursing notes is given to show the general situation:

*Nurse's Notes.*—"Sept. 10: Pale, slender baby who has no obvious abnormalities was admitted with temperature of 100° F. She ate a moderate amount of supper—pabulum, fruit, drank milk from cup. Slept fairly well.

"Sept. 11: Listless and sick. Took cold fluids, but refused solids. Went for x-rays.

"Sept. 12: Much better this A. M. Ate her breakfast well, watched children in Nursery School. Pointed to pictures of dog and boy and handled small toys. Is a listless and apathetic baby. She stands and walks with slight support. She refused all her dinner and ate her supper well. Evidently prefers cereal and fruit meals to meat and vegetable meals.

"Sept. 13: Crept a little, sitting down. Appears weak and sickly, rather than stupid.

"Sept. 14: Feeding difficulties more obvious. Does not wish dinner food. Seems more vigorous. She uses a few words, uses toilet sometimes and refuses to other times and screams.

"Sept. 16: Started on self-selected diet.

"Sept. 18: More vigorous and active and less willing just to look on. Puts pegs in holes, looks at pictures and moves around with vigor. Likes to walk with one hand support. Says 'Thank you,' 'doggie,' 'daddy.'

"Sept. 22: Using spoon well, but makes no attempt to hold cup yet. Attitude toward meals good and she is always ready for them. Stiffens and trembles at a sharp noise. She doesn't seem to be of convulsive nature, but more just very sensitive. Plays with the other children and is gaining in strength and abilities steadily.

"Sept. 24: When her shoes were put on, she said 'shoes' after me as I said 'new shoes.' She is walking much better with the shoes on.

"Sept. 25: Viosterol started and taken well on a bit of cracker. She cries in her sleep occasionally and chews on fingers, but is teething.

"Sept. 28: Threw sand about and tried to imitate the other children in making sand cakes.

"Sept. 29: Now walks alone pushing light doll carriage.

"Sept. 30: Social with everyone now. She greets us in the morning with a grin and 'Hi.' She uses more words—'dollie, doggie, shoes, socks, nice, all-gone.' She loves to be played with and is determined and easily made mad when she doesn't achieve desired end promptly. Bowels loose.

"Oct. 1: She was yelling to go to the dining room table at 7.30 A. M. She has a slight cold.

"Oct. 3: She handles her cup if it is only one-half full and she continues to progress toward independent walking. She tries to stand alone from a sitting position, but the floor is too slippery. She walks with whoever will loan her a finger.

"Oct. 5: Uses kiddie car effectively outside and rode herself to the sandbox where she started digging. Today she stands entirely unaided. She is taken off the self-selective diet as it seems no longer necessary and she has the ordinary diet. She still has some coryza; she is not sick, but emotionally unstable, cries and is petulant when she has to wait or is crossed.

"Oct. 9: She is happy, talking and laughing. She eats with a good appetite and handles her spoon well for her age. Her cup is taken well but is supported only if one-half full. Her vocabulary is increasing and is very near to entirely independent talking. She is not reliable in bowel and bladder control and makes no effort to tell her toilet wants (training has been erratic at best). She is easily startled and upset, but nothing of the nature of a convulsion has been observed. Discharged home."

The summary of the psychologist's notes indicates the field of inquiry as well as the results of more technical tests.

*Psychologist's Notes.*—"Mother 'waited five years for a baby.' As she was too ill to nurse the baby, the grandmother took care of G. until the child was three months old. The mother consequently felt insecure about feedings from the beginning. At six months G. refused solid foods, couldn't take Cod Liver Oil. Mother tried tentatively various methods of persuading G. to eat, but without success and each meal ended with the bottle. Mother never 'had courage to let the child go more than one meal without food.' The problem was further complicated by convulsions. My impression is that the mother's anxiety developed out of a real feeding difficulty, not created by her attitude."

*Mental Tests.*—"The child does not walk alone, but she can step along supported by one hand. If left standing by her pen she soon tries. (? muscular weakness.) In general her play with test material was between 15-18 months. Her language is also up to age. According to the mother the baby used three or four words on admission and she has added a few more frequently. As she grows stronger the prevailing mood has changed. When she first came, she solemnly watched what was going on and now one often sees her laughing.

"Unusual concessions have been made to the feeding problem—the self-selective diet. The mother has watched the child eat here and was very much pleased with the result. She probably would not have had the courage to permit such a variation from the usual diet for a child, but if the child gains she may be able to carry it out at home—more particularly if she can feed herself before she leaves the hospital. The mother is not impatient to have her at home under the circumstances, but she thinks she can manage to carry out the hospital instructions without interference from other members of the family. The father is away all day and the grandmother does not live at the house."

**Summary.**—Back of these summaries are adequate records which show the steady advance. When the child was discharged we were able to do, with full honesty, several things.

1 The presumption that the reported attacks were epileptic was discredited. The probability that they represented reactive disturbances was established.

2 The feeding problem, which had produced malnutrition recognizable on physical examination, was solved and we had every reason to expect that the parents could carry on from where we left

3. The suggestion that the mental development of the child was inadequate was discredited, not by authority, but by clear evidence of advance.

4. The groundwork for a durable revision of attitude and management was laid.

On discharge it was possible to transfer the care of the child to a mother who was no longer anxious or tired. She was shown, rather than told what to do.

These cases are all recent and in none of them was an inordinate amount of time necessary to arrive at an adequate decision. Naturally they are all to be followed, but our subsequent supervision of procedure is far more confident than it would have been without a ward study.

Of course no one expects the practitioner of medicine to have a psychologist at his elbow on his rounds. The point which seems to me clear is that he should arrange matters so that he is able to form his own opinion on the nature of the phenomena which are reported to him. The man who relies on hearsay about behavior is in as weak a position as the man who relies on a telephone to interpret physical signs. Naturally it takes time and space to observe behavior, but those who feel that the study is worth while will not find the expenditure unlimited.

The 3 cases discussed do not illustrate a method of preventing mental disease. I am quite incapable of producing cases where efforts directed to such an end are in progress. It seems to me clear, however, that all three of these children were seen at a time when "maladjustment" was already evident and I believe there is reasonable ground for supposing that our intervention and continued supervision is going to improve their chances of orderly growth and development.

## CLINIC OF DR. JOSEPH GARLAND

### MASSACHUSETTS GENERAL HOSPITAL

---

#### COMMON ERRORS IN PEDIATRIC DIAGNOSIS

THERE is for each of us, probably, according to our several abilities, an irreducible minimum of diagnostic errors which we will make as we go from patient to patient. Our obligation is to try to scale down to this minimum, deriving what profit we can from our errors and those of others, in order that they should not be a total loss to ourselves and to the community. It is not so important to know what errors to avoid, although this information has its value, as how best to avoid errors in general.

It may not be out of place to state, in this relation, that it is safer for the patient and one's own reputation to doubt one's diagnostic ability than to be too sure of it. To be over-sure invites a carelessness in our stewardship of other individuals' lives and welfare that may be fatal. The unconfident and unassured physician who ponders overmuch about his cases and calls often for help may not arouse our admiration, but unless he is completely paralyzed by indecision he does not deserve our contempt. Indeed, the patient is safer in his hands than in those of his colleague with an Hippocrates complex who questions all men's ability but his own and feels that he knows everything because he has learned nothing new. The physician whose word has for years been law to a devoted following is sometimes in danger of falling into this error—less often in a medically intellectual center than in a community where he has had to rely too completely upon his own resources.

An attempt to list all the errors in pediatric practice that

might be called common would be hopeless, and definite lessons can be learned from some of the less common ones, whether they are spectacular or otherwise. It is of greater importance to analyze the causes for making errors that should reasonably be avoided and to determine the method of their avoidance.

There are certain inescapable reasons for the fact that medicine is a scientific art rather than an exact science, and on this basis I should predicate five causes for diagnostic errors in any branch of the art, although we are at the moment dealing particularly with pediatrics.

These are in approximately the following order:

First, carelessness, which is theoretically inexcusable, but to which we are all susceptible in a degree dependent on our inherited characteristics and early training.

Second, lack of available knowledge, which is frequently excusable but not below a varying, moderate level.

Third, lack of an innate or painstakingly acquired ability to draw on the knowledge which we possess and to place the correct interpretation on the information which we have elicited—and to a greater or less degree we all have our intellectual blind spots.

Fourth, lack of accessory diagnostic facilities that under certain conditions may be beyond our power to obtain. We should, however, at least know those that are necessary or desirable to employ in a given case, under which conditions the correct diagnosis should be suspected even if it cannot at the moment be confirmed, and

Fifth, the other unpredictable human factor; the patient himself with his individual characteristics, his heredity and his environmental influences; in other words, the factors that make him react in his own way to the conditions that have been imposed upon him.

It is necessary, therefore, if we are to reduce our mistakes to a minimum, to take a reasonably exact and sufficiently complete history, depending on how complicated the case is and how obscure the diagnosis, as well as the importance of the

decisions contingent upon the diagnosis. Very little history is necessary in making a diagnosis of acute tonsillitis, but much more is needed in deciding on the advisability of a tonsillectomy or the possible presence of a rheumatic infection. It must be remembered that in pediatrics the historical data are objective rather than subjective; the facts are usually derived wholly or in part through an interested third party.

The physical examination should be carefully, even if rapidly, made under all circumstances, for no physician can afford, because a given diagnosis is simply made, to run the risk of overlooking a complication or a coexisting pathologic condition. While routine methods are always desirable, it is often necessary, in dealing with young children, to elicit physical data in an apparently haphazard order, selecting the easiest and most casual approach to a difficult patient. The most disturbing examinations, usually those of the ears and throat, which are also the most diagnostically fruitful, should be reserved for the grand and often tempestuous climax.

It is not my province or purpose and should certainly be superfluous to attempt to describe the physical examination of a child. Examination of the ears, however, deserves emphasis and the physician who assumes the care of children should have the necessary equipment and training to undertake this examination. Too often we find that the diagnosis of acute otitis media has been first made when the ears begin to drain. We may assume that the mouth and throat are usually inspected, but frequently the presence of a cervical adenitis is overlooked with disastrous results so far as diagnostic accuracy is concerned.

One of our medical Nestors said on a certain occasion that the chief functions of a consultant are to make a rectal examination and console the family of the patient. The rectal examination is not so often essential in pediatrics as it is in internal medicine or in surgery, but it is always indicated in rectal bleeding, which may be due to polyps, piles, or fissures, or where a surgical abdominal condition is suspected.

Many of the peculiarities of the human mind and body

are still beyond the range of any knowledge, but nevertheless a vast reservoir of available information exists that is being constantly added to, corrected and brought up to date. No one has all of this material, even in his chosen field, at his immediate command. The able pediatric consultant should be at least familiar with the bulk of the practical knowledge in his specialty; the practicing pediatrician should know much of it and should know something about most of the rest; the general practitioner may be excused for a considerable degree of ignorance about much of the specialized data, but should have a working knowledge of the common conditions of childhood and a general idea of the principles of pediatric practice.

More than a fund of knowledge, however, is necessary in the practice of medicine. There must be the ability to cerebrate along the lines of that knowledge, coordinating it with the information that has been gained by careful observation. To the born physician this is very nearly instinctive; the rest of us must acquire it through patience, perseverance and rigid mental discipline. It once was said of a well-known physician that his analyses of cases were marvels of logical deduction, but his chief value as a consultant was that the patient never had the disease he selected; his conclusions were always wrong. He had knowledge and industry, but no ability to combine the two, and knowledge without a certain amount of wisdom is a motor without a spark.

An excited practitioner brought a patient on the verge of tetanic convulsions to our hospital not many years ago. "Day before yesterday," he said, "this man complained of stiffness of the jaws. Yesterday it was worse. This morning it was still worse and he said to me, 'Doctor, do you suppose I have lockjaw?' 'Great Scott,' I said, 'why didn't you mention that before? I never thought of it!'"

Laboratory facilities have become a recognized part of our modern diagnostic armamentarium, and the patient has a right to their aid when they are indicated and where they are available. The doctor must decide when they are indicated, recognizing also that superfluous ones merely gild the lily and

empty the patient's pocketbook. Too often, I am afraid, necessary procedures are neglected because they are not *easily* available. There are few patients who cannot by some means be transported to a good hospital once the necessity for it is seen and acted upon, but not infrequently we encounter cases that have been wrongly diagnosed and incorrectly treated for weeks before the effort is made to procure the best service possible for them.

Even if these facilities cannot be immediately procured the physician with a reasonable amount of knowledge and a reasonable degree of wisdom will have decided upon the procedures he believes necessary to confirm the diagnosis that he is considering. He will himself, of course, have the means for making blood counts, analyzing the urine, and performing the tuberculin test.

Last, and not the least difficult, comes the appraisal of the individual who is harboring a disease the nature of which we are trying to determine, and here a knowledge of the patient and his family may be of great assistance. More information, both in the history and on the physical examination can be obtained from the cooperative and well-adjusted child than from the spoiled, resistive and emotional one. The shape of the jaws and the expression of the face may denote an abundance of adenoid tissue and a susceptibility to upper respiratory infection; body build and body mechanics may suggest the common enemy of modern childhood—chronic fatigue.

One of the commonest errors in pediatric practice is to attribute all the nutritional disturbances of infants to improper diet. Many infants are weaned from the breast or have their formulas changed from one mixture to another, from one proprietary food to the next one, when all they need is to be given enough of nearly any type of food to satisfy their hunger, or to have the environment so changed that they can live in peace within it.

Two out of 5 babies who are colicky, wakeful, unhappy and vomiting are hungry. They are being given insufficient amounts of food, usually too dilute, often in too many feedings

and frequently at too short intervals. Overfeeding or an unsuitable formula is the ready diagnosis, a diagnosis quite probably insisted upon by the mother or nurse, and the round of experiments commences, usually with a food still more highly diluted.

Two more out of the 5 are reacting strenuously to an environment which does not allow them sufficient opportunity or time to vegetate—to rest and to sleep. The baby is used either as an animated human exhibit for friends, relatives and the bridge club, or it is expected to slumber through an atmosphere charged with the high voltage of anxiety. The response is apt to reflect the results of overstimulation—hypertonicity, fatigue and reflex digestive disturbances, and the treatment usually consists of a change in formula.

The last one of the 5 may suffer from the results of a food either grossly improper for any comparable infant or specifically unsuitable for the individual. A fat or sugar intolerance will manifest itself by vomiting and diarrhea or both, with presumably failure to gain in weight, or by colic and restlessness. If adjustment of these principles does not effect an improvement, an allergic reaction to milk protein may be suspected. Gross overfeeding may cause difficulties; most infants will sensibly refuse or reject food that they do not need.

Appendicitis is a condition that has stirred both medical and popular fancy sufficiently for decades so that by now one would suppose few mistakes should be made in its diagnosis. Acute surgical conditions of the abdomen in children are notoriously uncertain in their signs and symptoms, however, and various writers have shown that a real menace attends a complacent attitude toward abdominal pain. Hudson<sup>1</sup> has pointed out that in Massachusetts between 1900 and 1930 child deaths from appendicitis have increased 428 per cent during a period in which the child population increased only 41 per cent. In 1919 the disease did not appear among the first 10 causes of death, but from 1926 to 1930 ranked eighth, and for the longer period, 1926 to 1933, occupied fifth place in the age group one to nine.

It is wise always to consider first the possibility of appendicitis when the classical triad of symptoms, abdominal pain, vomiting, and fever occurs, and to avoid any tendency to adopt a casual rather than a watchful policy of expectancy. Hudson found that pain was the most common symptom, occurring in 99 per cent of the patients observed. It may, however, be poorly localized or complained of only on micturition or defecation, and it need not be severe. Local tenderness was found in 94 per cent of these patients and the necessity of a rectal examination was emphasized.

Muscle spasm Hudson found in 83 per cent of his patients studied, but "to appreciate muscle spasm in the child, patient approach, prolonged examination and experience in the examination of children are necessary." The spasm may be of much less degree than will be found in the adult. Nausea or vomiting was noted in 92 per cent of these patients.

The fever usually ranges from 99° to 101° F. but with wide variations. In the obstructive forms of appendicitis fever may be absent. Leukocytosis is usually between 12,000 and 20,000 but again with the possibility of wide variations.

A differential diagnosis between acute appendicitis and acute mesenteric adenitis may be practically impossible to make, and, if there is doubt, operation represents the conservative decision. Inflammation of the peritoneum primarily infected, as from the pneumococcus, can rarely be distinguished from inflammation secondary to appendiceal involvement. Rheumatic fever may cause abdominal pain closely simulating an attack of appendicitis; in some cases in which laparotomy has been performed inflammation of the diaphragmatic peritoneum has been found; in others, nothing. Infections of the upper urinary tract must be excluded by examination of the urine and this should always be done where appendicitis is suspected.

It is well to bear in mind, also, that appendicitis may co-exist with or result from other infectious diseases. The incidence of appendicitis is likely to rise when upper respiratory diseases are prevalent, and Hudson and Krakower<sup>2</sup> have noted

an association with measles which is more than coincidence, reporting 8 such cases.

Pneumonia is the classical disease which, at its onset, may simulate nearly any acute infection, but particularly appendicitis and meningitis. A boy of five who was seen a few years ago had for three days been delirious with high fever, stiff neck, and a positive Kernig sign. A tentative diagnosis of meningitis was made and he was sent to the hospital, where lumbar puncture disclosed a normal spinal fluid. Four days later a patch of bronchial breathing appeared in one axilla and x-ray revealed complete consolidation of a lobe.

Adams and Berger<sup>3</sup> some time ago called attention to the frequency with which pneumonia is mistaken for appendicitis, and today nearly every pediatric house officer boasts of the occasions (perhaps largely imaginary) when he has rescued pneumonia patients from the trucks on their way to the operating amphitheater. These authors found that abdominal pain, vomiting and diarrhea occur as frequently in pneumonia as in abdominal conditions. The pneumonia patient, however, always seems more ill and shows much more of a systemic reaction as evidenced by pulse and temperature chart than does the abdominal case.

A high leukocyte count (over 20,000) favors the diagnosis of pneumonia against that of appendicitis before rupture. In pneumonia abdominal tenderness seems more severe, but less localized; "frequently the child jumps or cries as soon as the abdomen is touched, and deeper pressure does not add to the discomfort; the part affected seems superficial rather than deep, and at times almost suggests a hyperesthesia. The tenderness in the uncomplicated appendicitis case may be slight; it is always less impressive than that of a pneumonia, and is more readily localized, usually to a small area in the right lower quadrant."

When any infectious disease is prevalent in a locality, a diagnosis under consideration is more likely to fall into that group than would otherwise be the case, particularly if the epidemic disease is common and widespread. Certainly the

epidemic infection must be considered and excluded, if there is doubt, before the diagnosis is established on some other basis. Mistakes are commonly being made, however, in concluding too casually that the disease in question belongs in the prevalent group.

A dramatic or especially dreaded disease may assume undue importance in the minds of both the laity and the medical profession even if its epidemic incidence is far below that of less spectacular conditions such as the upper respiratory infections or measles. During one of our recent outbreaks of anterior poliomyelitis two respected physicians in a neighboring town decided in consultation that a certain boy had the disease. An agent of the infantile paralysis commission, called to see the case, was forced to point out as tactfully as possible that the child had an injected pharynx and acute cervical adenitis—sufficient cause for the stiff neck of which he complained. A careful physical examination and a little deductive reasoning should have been sufficient to have established this diagnosis in the first place.

Another agent of the commission, during the same epidemic season, was called to some distance in considerable haste to assist in the salvage of a paralyzed case. On arrival he found an elderly gentleman who had just sustained a cerebral hemorrhage with resulting hemiplegia!

Due to the panic incident on its arrival, no disease is suspected in so great a variety of types of infection as is infantile paralysis. Fond parents are largely responsible for this, for they see a stiff neck or a rigid back in any condition, and the lameness resulting from a stone bruise is sufficient excuse to bring the doctor out at any hour of the day or night. The amount of back raising and neck bending that healthy children are subjected to at these times is enough to give a degree of muscular lameness about the vertebral column, and the implication with which these calisthenics are associated can easily bring the rest of the symptoms to the mind of the patient.

In general, diseases of the respiratory tract and their complications lend themselves most readily to diagnostic errors.

This is due partly to inadequate examination, particularly of the pharynx, tympanic membranes and cervical lymph nodes, and partly to the great difficulty, with children, of finding and interpreting pulmonary signs. If a temperature of undetermined origin remains elevated for more than two or three days, especially if any signs of an upper respiratory infection are present, pneumonia should be suspected, regardless of a low respiratory rate and any condition of well- or ill-being of the patient. Frequently the roentgen ray will be necessary to confirm the diagnosis and frequently the diagnosis of pneumonia, if made, will be wrong.

Other pulmonary conditions of childhood, also, may tend to confuse the diagnosis; lung abscess, bronchiectasis, foreign body and tuberculosis.

To show that the diagnosis of a simple upper respiratory infection may also present peculiar difficulties, it is pertinent to refer to Wallgren's<sup>4</sup> remarks concerning the development of allergy in primary tuberculous infection. The period of incubation between the time of penetration of the tubercle bacillus and the appearance of allergy may vary, probably, from three to seven weeks. During this period a diagnosis cannot be made clinically, although if tuberculosis is suspected the bacilli may be found in gastric washings.

With the appearance of allergy, fever may develop, but this rise in temperature resembles the ordinary fever accompanying a cold, and is usually mistaken for one. It may be moderate in degree or may reach a height of 104° F. The onset may be insidious or it may begin suddenly, as in an influenza infection. The course may differ in no way from that of the familiar acute infections.

The distinguishing feature of this phenomenon is that with the appearance of allergy the tuberculin test first becomes positive, and at this stage the sensitivity to tuberculin, previously not present at all, may be greater than at any subsequent time. The delicate intracutaneous test is not necessary at this time to produce a positive reaction of considerable degree. The cutaneous Pirquet test and the percutaneous test with ointment

are sufficiently reliable to arouse the reaction. Erythema nodosum may also occur at this stage, although it is apparently much less common in this country than in Scandinavia. It may not be due to tuberculosis, but its appearance always demands a tuberculin test.

Not long ago I was asked to see, at a suburban hospital, a child suspected of having purpura haemorrhagica. This patient had had fever for the better part of a week, but all physical signs, including x-ray examination, were normal except for a typical erythema nodosum. A tuberculin test was requested but the parents withdrew the child from the institution and brought her to a Boston hospital, where she died within ten days of tuberculous meningitis.

Less common diagnostic errors than these types noted may also point a moral or at least adorn a tale. A surgical colleague went into the country to see an infant on whom a diagnosis of osteomyelitis had been made, or at least suggested. One does not commonly see scurvy in a breast-fed infant, but it happened to fulfil the diagnostic requirements in this particular case.

During a recent epidemic season an infant was sent to me with the diagnosis of poliomyelitis and presumable involvement of both legs. There was unquestionably pain in the legs when they were manipulated, but no paralysis, as the baby kept them firmly flexed on the abdomen. A short history elicited the information that this bottle-fed infant had had no orange juice for several months, and x-ray of the extremities showed typical lines of scurvy and periosteal elevation. Orange juice quickly changed the picture—a therapeutic test which is in everyone's hands.

One sees every so often typical Mongolian idiots who have been hopefully but fruitlessly fed thyroid extract under the impression that they are cretins; reference to a text will usually clarify the doubtful diagnostic points, even if an infant metabolism apparatus is not available. In convulsive cases tetany should at least be considered in infants, and lead poisoning in older children. A careful history may direct suspicion to

either of these conditions, which laboratory tests or a roentgen ray may confirm.

A citation of types or examples of errors leads inevitably to our original premise, that avoidable errors can be reduced in number only by careful histories and examinations and the employment of accessory diagnostic facilities when indicated and where available.

### THE DIET DURING PREGNANCY AND THE NURSING PERIOD

THE last two decades have seen increasing emphasis placed upon the regulation of diet in the maintenance of health as well as in the treatment of disease. This increasing attention to nutrition has been the logical outcome of a galaxy of discoveries both in the fields of nutrition and of clinical medicine. Researches in experimental nutrition have led to a keener insight into the precise nutritional requirements of the body in such terms as total energy, protein, minerals and vitamins. In the field of medicine, a number of previously baffling diseases have been finally recognized as the result of dietary deficiencies, or defective alimentation of potentially adequate diets, or both. Thus, such varying disorders as pernicious anemia, pellagra, Korsakoff's syndrome, and the polyneuritis which develops after prolonged hyperemesis gravidarum have been shown to respond to specific dietary measures. Advances are rapidly being made in the recognition of a number of relatively commonplace "subclinical" nutritional disorders, such as mild scurvy, dental caries, nutritional anemias and edema.

The physiologic states of pregnancy and lactation make special nutritional demands upon the mother. At the same time, at least during pregnancy, alimentation is often less efficient than during the nonpregnant state. This is indicated

by the incidence of nausea and vomiting, the frequency of hypochlorhydria and constipation. The combination of these special demands with defective alimentation make meticulous attention to the diet during these periods doubly important.

In the clinical application of the science and art of nutrition to pregnancy and lactation, one should remember that a number of the standards set as requirements are to some extent arbitrary. Common sense tells us that women have had babies and have nursed them without the daily consumption of a whole quart of milk, and yet have escaped total nutritional collapse. On the other hand, inappropriate diet during pregnancy and lactation often leads to poor maternal health and not infrequently to serious consequences for mother and child.

The demands of the baby and the altered maternal metabolism during pregnancy and lactation result in such marked changes in nutritional requirements that these are not necessarily met by food habits which are optimum for a woman at reproductive rest. The average American diet, particularly that of women in the lower economic group, is often seriously deficient in a number of the essentials during these periods. While diets suitable for pregnancy and lactation are essentially normal qualitatively, the quantitative needs for total calories, protein, minerals, vitamins, and even water are considerably altered by these functions.

It will be remembered that the fetus in utero is essentially parasitic. It takes what it needs from the mother's blood stream regardless of her food intake. Thus when the maternal diet is inadequate, or even in the presence of an adequate diet, when absorption from the gastro-intestinal tract is defective, the maternal organism serves at its own expense as a buffer between the inadequate food absorbed and that taken from the maternal blood stream by the fetus. The cost to the mother in terms of demineralization, nitrogen loss and vitamin deficiency may be tremendous, with attendant serious consequences, such as dental caries, anemia, and even osteomalacia. The fetus suffers only if its immediate source of nutrition is depleted, a state of affairs which can exist only following pro-

longed and definitely harmful inadequacies in the maternal diet. Thus a restricted maternal diet can have little or no effect upon the weight of the fetus unless the restrictions are prolonged and dangerously excessive. This was well illustrated by the maintenance of average birth weights of babies in Germany during the war.

As a preliminary to a discussion of the practical aspects of prescribing a diet during pregnancy and lactation, it will be helpful to present, briefly and specifically, the altered needs for the several components of the diet which are brought about by these physiologic states. In doing this no attempt will be made to review the literature on this subject. For an exhaustive review of nutrition during pregnancy and lactation the reader is referred to the excellent summary of Garry and Stiven,<sup>1</sup> on which we shall lean heavily in the subsequent discussion.

**Energy Requirement.**—The basal metabolism of the pregnant woman has been repeatedly investigated. The results of these studies indicate that the basal rate tends to increase steadily from about the fifth or sixth month of pregnancy. Shortly before term it is about 23 per cent higher than in the nonpregnant woman. It has been shown that the basal metabolism of the pregnant woman just prior to parturition is equal to that of the mother and child taken separately three to ten days after the birth of the child.

The increased need in the quantity of food consumed during the early months of pregnancy is so slight as to be negligible. Even during the latter months of pregnancy, when the growth of the fetus is rapid, the total caloric requirements are never more than approximately 20 per cent above normal; for while the basal requirement is increased some 23 per cent this is partially offset by the diminished activity common to the third trimester. During the period of lactation there is a greater increase in the total energy requirement. This larger demand during the nursing period may be explained as follows:

- a. Sufficient fuel to meet the mother's own energy requirement.

- (b) Food equivalent in caloric value to the milk produced.  
(Twenty calories per ounce of milk produced.)
- (c) Fuel to supply the energy required to produce milk.  
(Equivalent to approximately 10 per cent of the fuel value of the milk produced.)

We feel that the caloric requirements commonly given for diets during the periods of pregnancy and lactation are often too high. Our clinic observations would suggest that further study along these lines would result in a revision downward of the so-called "standard energy requirements" for these periods. The average total energy requirement during pregnancy will be found to be from 2200 to 2600 calories; and during lactation from 2800 to 3200. Variations of these schedules will, of course, be necessary with reference to the size and activity of the woman concerned.

**Weight Gain During Pregnancy.**—A total weight gain for the period of pregnancy of from 16 to 20 pounds above normal weight for the individual is considered desirable. Provided that the retention of water is not excessive, the above represents the average loss during the first two weeks of the puerperium. Excessive weight gain during pregnancy should be avoided, for in addition to the esthetic objections, it is associated with a definitely increased incidence of dystocia, and probably also with increased incidence of toxemia. It is not yet entirely clear how much of the excessive weight gain associated with toxemia is due to water retention, although overeating and obesity would seem to play definite rôles. The ineffectiveness of dietary restrictions within safe limits in controlling the size of the baby has already been mentioned.

**Carbohydrates.**—During the past fifteen years hyperemesis gravidarum, preeclampsia and eclampsia have been attributed by various writers to disturbances in carbohydrate metabolism. While there is an increase in the total energy requirement during the later months of pregnancy, there is no conclusive evidence that carbohydrate is important other than as a source of energy during pregnancy. Although extra energy is needed during the lactating period, the concentration

of lactose in breast milk is very constant, and has been shown to be very little affected by the nature of the diet of the mother. There is some evidence to indicate that a high carbohydrate intake, during the nursing period, may tend to inhibit milk production.

**Fats and Lipoids.**—Very little is known about the metabolism of fats and lipoids during pregnancy and lactation. However, that changes occur during pregnancy involving fats and lipoids is indicated by the ease with which the level of acetone bodies is increased in the blood, the elevation of the level of blood cholesterol, and the ease with which (compensated) acidosis occurs, as indicated by the appearance of acetone bodies in the urine. Certain lipoids and fatty acids would appear to be essential to the diet at all times, as, for example, linoleic acid. Aside from its chief function as a source of energy, fat is of importance as a carrier of the fat-soluble vitamins A, D and E.

**Proteins.**—During pregnancy an increased requirement for protein is shown by the significant retention of nitrogen. Indeed, in so far as the few balance studies go, it would appear that considerably more nitrogen is retained than may be accounted for by the development of the fetus. Thus, in the studies of Macy and her coworkers,<sup>2</sup> it has been shown that with an average ingestion of 19 Gm. of nitrogen from proteins of excellent quality, there was a resultant mean net retention of 3.1 Gm. of nitrogen per day, representing a storage of 16 per cent of the nitrogen intake during the last one hundred and forty-five days of pregnancy. In this experiment, the subject's ability to retain an abundance of nitrogen was further shown by the fact that she stored 2.6 Gm. of nitrogen daily, beyond the calculated amount utilized by the developing ovum. The total observed accumulation was 446 Gm. at term. A compilation of statistics from other nitrogen balance studies gives the average daily nitrogen retention throughout pregnancy as 2.28 Gm., equivalent to the retention of 14.25 Gm. of protein daily. The authors state that from comparison of the two sets of data, it would seem that, in general, the richer

the diet in protein of good biological value, such as from milk and its products, the greater was the persistent storage of nitrogen during pregnancy. From their continued metabolic studies during a large part of the reproductive cycle, Macy and her associates have also shown that in some multiparae there is negative nitrogen balance during early lactation. It is also interesting to note that these women who were on high protein intakes gave high milk yields during the nursing period. It has long been known, in the dairy industry, that a high protein diet begun late in gestation in cows improves their milk yield. Other workers have also drawn attention to the fact that in women the greater the retention of nitrogen in the latter part of pregnancy, the greater the likelihood that there will be a sufficient milk supply. Certainly there is adequate experimental as well as clinical data to substantiate the idea that there is increased need for protein, particularly during the latter part of pregnancy and during lactation.

There has been a general impression that the toxemias of pregnancy are related to the protein in the diet. For this reason many obstetricians have restricted the protein intake during pregnancy. According to some investigators, toxic substances which may be harmful are formed in the breaking down of proteins, especially meat protein. On the other hand, in a recent paper Strauss<sup>3</sup> suggests that a diet low in protein may be the cause of toxemia, and he reports cases successfully treated with high protein diets. These diets were supplemented by vitamin B and liver. Certainly there is no satisfactory evidence that a liberal protein intake during pregnancy is the cause of toxemia in normal women. On the other hand marked restriction of protein over prolonged periods during pregnancy and lactation may result in diminished serum proteins with attendant edema, negative nitrogen balance, and indirectly, anemia.

An optimal intake of protein during pregnancy is approximately 100 Gm. per day. The League of Nations Technical Commission gives 2 Gm. per kilogram of body weight as a desirable intake. Animal proteins, because they are rich in

the essential amino acids should be emphasized. If the daily diet contains 1 quart of milk, a liberal serving of meat, and an egg, together with the amount of protein in the other foods of a well-balanced diet, the mother's need should be well covered. During the period of lactation protein is utilized in the production of milk, and a high protein intake is known to favor milk production. The optimum daily intake during lactation should be approximately 125 Gm. of protein of good biological value.

**Minerals.**—The 3 minerals, calcium, phosphorus and iron, which require special attention in the normal diet, need added emphasis during the periods of pregnancy and lactation. In goiter zones iodine also requires attention.

**Calcium and Phosphorus.**—The demand for calcium and phosphorus during both the periods of pregnancy and lactation is approximately doubled. During the first trimester of pregnancy this increased need is slight. By the fourth month, however, calcium and phosphorus are being deposited in most of the bones of the fetus, and the teeth are forming. All of the temporary teeth are formed during the prenatal period. The deposition of calcium and phosphorus in the fetus is greatest in the third trimester of gestation.

Not only are the amounts of calcium and phosphorus in the diet important, but their utilization is intimately related to the ratio of Ca:P, as well as to the vitamin D intake. If vitamin D is administered in very large amounts, a significantly greater proportion of the ingested calcium and phosphorus are retained by the body. Thus, a high intake of vitamin D may materially reduce the needed intake of calcium and phosphorus. However, until the physiologic responses to excessive amounts of vitamin D are better understood, some caution should be exercised in its use. Inadequacy or maladjustment of these factors during pregnancy and lactation may result in such conditions as dental decay, osteoporosis and rickets.

The results of metabolism studies, during pregnancy and lactation indicate that a higher intake of calcium and phos-

phorus than that of most women favors retention of calcium and phosphorus both in the mother and fetus. During pregnancy an intake of at least 1 to 1.5 Gm. of calcium daily, and about 1.5 to 2 Gm. of phosphorus seem advisable. The requirements for both calcium and phosphorus during lactation are probably even higher. Since milk is our best food source of calcium, it should be used liberally in the diet throughout these periods. Cheese, with the exception of cottage cheese, is also an excellent source. In general, the vegetables and fruits are good sources of calcium, adding materially to the calcium content of the diet, when taken in liberal amounts. Phosphorus is more widely distributed in foods than is calcium, and so is less apt to be deficient in the average diet. If the diet is liberally supplied with protein, as already suggested, the phosphorus needs during pregnancy and lactation will be well met.

*Iron.*—During pregnancy and lactation the iron requirement is increased at least 20 per cent. Considering the adult's normal daily requirement for iron as 15 mg., there should be at least 18 mg. in the diet of the pregnant and lactating woman. This amount of iron is necessary during pregnancy to prevent anemia in the mother. The fetus abstracts considerable iron from the maternal blood both for maintenance of a normal hemoglobin level in its blood, and for iron storage in its liver. This iron stored during later intra-uterine life serves as a reserve during the early months of extra-uterine existence, when milk, which is poor in iron, is the major food of the baby's diet. The White House Conference publication, "Nutrition," states that the child at birth has in its body 375 mg. of iron, which it has secured by daily transfer from the mother: this is said to be brought about by a transfer of about 0.4 mg. daily during the early part of pregnancy, and 4.7 mg. daily during the third trimester. This large drain upon the mother, especially in the latter part of pregnancy, together with diets often inadequately supplied with iron-rich foods may account in part, for the microcytic hypochromic anemias so commonly found in pregnancy. The diet should, therefore, be liberally

supplied with iron-rich foods throughout this period. The foods richest in iron are liver, kidney, lean meat, egg yolk, apricots, prunes, peaches, green leafy vegetables, and molasses. The whole grain breads and cereals are good sources of iron. In considering the iron-rich foods one should bear in mind the fact that certain foods are superior to others in their power to build hemoglobin, and that this is not necessarily dependent upon their iron content. Liver, kidney, apricots and peaches illustrate this fact; liver and kidney being superior to lean meat, and apricots and peaches superior to spinach. In addition to a liberal use of foods rich in iron, the authors recommend that patients be given moderate doses of iron during pregnancy (as, for example, ferrous sulphate, 3 grains three times a day).

*Other Minerals.*—In those regions where goiter is not endemic an adequate amount of iodine is obtained from the local water and foods when a well-balanced diet is eaten. The other minerals required do not usually need special attention. Salt (NaCl) sometimes needs restriction in the latter months of pregnancy if weight gain is accompanied by edema.

*Water.*—An adequate amount of water should be taken daily during pregnancy and lactation. A liberal fluid intake aids in the digestion and absorption of food and helps to prevent constipation. Liberal water intake also is of considerable prophylactic value in the prevention of pyelitis. During the early part of pregnancy an intake of from 6 to 8 glasses of water daily is usually well tolerated, but during the last trimester, especially when edema occurs, restriction of fluid intake may be advisable.

Cellulose is necessary for normal intestinal function. It is also of benefit to satisfy appetite where calorie intake is restricted. A sufficient quantity of cellulose is obtained when vegetables, fruit, and whole grain products are included liberally in the diet. However, the indiscriminate use of large quantities of roughage, such as bran, not infrequently results in troublesome intestinal irritability.

*Vitamins.*—Vitamin A is essential for normal growth and

development, as well as for reproduction. Deficiency is manifested pathologically by keratinization of the body epithelia with resultant increased susceptibility to infection. There is some clinical evidence that a lack of vitamin A in early pregnancy may cause resorption of the fetus, or later increase the incidence of premature or still births. It is also possible that there may be some relationship between vitamin A and the incidence of puerperal sepsis. While the body has the ability to store vitamin A in relatively large quantities, the demand for this vitamin during the reproductive period is greatly increased, and unless the diet includes a liberal amount deficiency may develop. The best food sources of vitamin A are whole milk, cream, butter, cheese, egg yolk, leafy green and yellow vegetables. Since vitamin A is fat-soluble, the practice of using skim milk to control weight gain during pregnancy greatly reduces the vitamin A content of the diet. If it becomes necessary to skim the milk or reduce the amount of butter in the normal diet of pregnancy, some adequate supplementary source of vitamin A should be supplied. Cod liver and halibut liver oils are concentrated sources of this vitamin as well as of vitamin D, and may be used. A diet high in vitamin A is desirable during the nursing period, since there is evidence that a direct relationship exists between the vitamin A content of the mother's diet and that of her milk.

*Vitamin B* ( $B_1$ ) in adequate amounts stimulates appetite and growth and is necessary for normal reproduction. When insufficiently supplied it may result in impaired neuromuscular control of the intestinal tract, often resulting in atonic constipation. Deficiency of vitamin B ( $B_1$ ) is an important secondary factor in hyperemesis gravidarum; in some prolonged and severe cases it would appear to contribute to the so-called "polyneuritis" of pregnancy. Foods rich in vitamin B ( $B_1$ ) are whole grain products, vegetables, fruits, milk and egg yolk. Brewer's yeast and wheat germ are concentrated sources and can be used when additional vitamin B ( $B_1$ ) is needed. The requirement for vitamin B ( $B_1$ ) is high during both pregnancy and lactation. The vitamin B ( $B_1$ ) content of breast milk is

largely dependent upon the vitamin B ( $B_1$ ) content of the mother's diet. Metabolism studies indicate that from three to five times as much vitamin B ( $B_1$ ) is necessary for lactation as for normal growth and maintenance. The increased requirement is probably nearly as great during pregnancy itself.

*Vitamin G* ( $B_2$ ) is found in many of the foods rich also in vitamin B ( $B_1$ ). Meat and milk contain more vitamin G ( $B_2$ ) than B ( $B_1$ ). If the diet is well supplied with meat and milk it will not be deficient in vitamin G ( $B_2$ ). Deficiency of vitamin G ( $B_2$ ) results in lack of vigor and premature senility. Pronounced deficiencies are associated with the etiology of pellagra and a type of macrocytic hyperchromic anemia. Pregnancy and lactation increase the need for this vitamin as is suggested by the observation that latent pellagra may become manifest during these periods. Furthermore, certain cases of macrocytic hyperchromic anemia during pregnancy respond promptly to the exhibition of this vitamin.

*Vitamin C*.—The requirement for this vitamin is increased both during pregnancy and lactation. In experimental work with guinea-pigs, on diets very deficient in vitamin C, the female does not conceive because of failure of ovulation. When the deficiency is less marked, abortion or resorption of the fetus takes place. The young of scorbutic does show signs of scurvy. Evidence of suboptimal intake of this vitamin among women is often seen in the condition of the teeth and gums. It also plays an important part in the bone and tooth development of the baby. Extreme deficiency results in scurvy. The diet should contain one or more excellent sources of vitamin C daily. Citrus fruits and tomatoes (raw or canned) are excellent sources. In using tomato juice instead of orange juice it takes at least twice as much of the former to give the same relative amount of vitamin C. Raw cabbage is also an excellent and inexpensive source of this vitamin.

*Vitamin D*.—As has been stated vitamin D in adequate amounts is important in promoting optimal utilization of calcium and phosphorus. Vitamin D has few good food sources. The best food oils are our best natural sources of this vitamin.

and are rich in vitamin A as well. Egg yolk is also considered a good source. The action of direct sunlight upon the skin is an important means of increasing the vitamin D content of the body. When vitamin D is furnished in optimum amounts, it helps to prevent fetal rickets, and facilitates the absorption of calcium and phosphorus. It is probably advisable for the pregnant woman to take cod liver oil, or its equivalent, throughout the period of pregnancy as a protection both to herself and her child. This is certainly true for the winter months when there is little natural ultraviolet radiation and the little vitamin D present in our natural foods may be further reduced. It is, probably, also wise to continue its use throughout the nursing period, but the amount transferred through breast milk to the baby is questionable and should be supplemented.

*Vitamin E.*—At the present time there is no clinical evidence that vitamin E is required by human beings. Experimentally with rats a diet deficient in vitamin E results in destruction of the germ cell in the male and failure of placental function in the female. This vitamin is widely distributed in food. It is found in wheat germs, seeds of plants, green leafy vegetables, muscle meat, and milk. Whether or not it is required in human nutrition, it seems probable that with this wide distribution of vitamin E the danger of shortage is slight.

**Practical Aspects of Dietary Instruction.**—From the foregoing discussion it is seen that while the total energy requirements during pregnancy and lactation are somewhat increased, there are strikingly disproportionate increases in the demands for protein, minerals, and vitamins. Failure to meet these changes often results in minor "subclinical" disturbances in health and not infrequently in serious consequences to mother and child. For these reasons clinical efforts should be made to see that these requirements are met.

Undoubtedly, a totally "naturally selected" diet would approach the optimum nutritional requirements of pregnancy and lactation. However, in considering the diets of civilized

people today, we cannot rely upon appetite as a guide in food selection as well as we could in primitive times, when all foods eaten were in their natural states. Indeed, the fact must be faced that modern diets are too often made up largely of milled, processed, and artificial foods. On the one hand, the consumption of milled and processed food has greatly increased. White flour and other milled cereal products from which most of the minerals and vitamins have been removed, form a large part of the diets of today. White sugar, the use of which has increased so tremendously in recent years has, also, in the refining process, lost valuable minerals still present to a large extent in molasses and brown sugar. On the other hand, while the same period has seen a marked increase in the consumption of fruits and vegetables, these are still consumed sparingly by a large proportion of the population, especially by families on low incomes. While the consumption of milk has increased, its daily per capita consumption is still very low in the light of our accepted standards of nutrition. The spending of a smaller proportion of the food budget for meat, white sugar and milled cereal products, and a greater proportion for milk, fruits, vegetables, eggs, and whole grain products, would do much to improve our nutrition. The dissemination of this knowledge through the instruction of pregnant and nursing mothers by the obstetrician, the pediatrician, the nutritionist, and by other workers in these fields, would do much to improve the health of our mothers, their children, and the family as a whole.

The nutritional demands of pregnancy and lactation, particularly the altered requirements for the several components of the diet, make clear the importance of careful instruction to pregnant and nursing mothers as to their daily food requirements. Indeed, no prenatal or postnatal care is adequate without such instruction. The patient should be questioned as to her customary daily food intake, her appetite, her food likes and dislikes, and her economic status. In the light of this information she may be shown those changes in her food habits which are both practical and advisable. When changes

## THE DAILY DIET DURING PREGNANCY AND LACTATION

*Milk:*

One quart daily is desirable throughout the period of pregnancy, and at least 1 quart during the nursing period.

Milk may be taken as a beverage with meals or between meals, or it may be cooked into the foods, as in cream soups, custards, creamed dishes, etc. Buttermilk may replace milk, and cheese may also be used in place of part of the milk.

*Vegetables:*

Two or more liberal servings daily of which at least one should be raw. (An ordinary serving equals 4 heaping tablespoonfuls [ $\frac{1}{2}$  measuring cup].) Leafy green vegetables, such as lettuce, spinach, cabbage, dandelion greens, chard, broccoli, etc., should be used daily. One potato is also desirable.

*Fruit:*

At least 2 servings daily. One of these should be a citrus fruit or tomato (raw or canned).

*Whole Grain Products:*

At least 2 servings daily of either whole grain bread or cereal. (One-half cup cereal = approximately 1 average slice bread.)

*Egg:*

One daily.

*Meat:*

One liberal serving of lean meat daily during pregnancy. Liver is valuable. Fish may occasionally be used instead of meat. Since a high-protein diet seems to favor milk production, meat, or its equivalent, may be used twice daily, during the nursing period.

*Butter:*

Should be used in moderate amounts.

*Cod Liver Oil:*

Or its equivalent, 2 teaspoonfuls daily. One of the accepted concentrates of fish liver oils in capsule form is acceptable.

*Additional Food:*

To meet daily energy requirements and food likes, remembering that much more food can be eaten during the nursing period than during the period of pregnancy without excessive weight gain. When there is a tendency to gain weight too rapidly, restrict foods rich in fats, sugars, or starches, such as gravies, bacon, mayonnaise, fat meats, macaroni, spaghetti, etc., rich desserts, as pies, pastries, cakes, too much ice cream, chocolate, candy, sweetened beverages, such as ginger ale, etc.

*Water:*

Six to 8 glasses daily unless there is need to restrict this amount during the latter part of pregnancy.

(It will, of course, be necessary, from time to time, to vary the above requirements to meet the individual needs of the patient.)

in food habits are advised the reasons for these changes should be explained in simple terms. Too much emphasis cannot be placed upon the fact that the difference between success and failure in obtaining the cooperation of the patient depends upon her intelligent appreciation of her dietary needs during pregnancy and lactation. This does not mean that she must have a detailed knowledge of food values, nor that she must sit down each day and check her diet for its quota of each one of the necessary components. A more practical method is for her to use a simple daily plan of feeding, expressed in certain foods or food groups, which will make certain that all the specific requirements are met. Such a plan as the one given on page 560 insures adequacy and yet permits much freedom in individual choice of food, while still teaching the patient the dietary essentials around which her daily menus should be planned.

It must be remembered that the consumption of the right amounts and kinds of foods is only a part of good nutrition. While the mother is learning good food habits she should be taught the value of proper rest, sleep, and exercise, all of which are so important to the establishment of good nutrition in its fullest sense.

## CLINIC OF DR. JOE VINCENT MEIGS

FROM THE SURGICAL SERVICES OF THE MASSACHUSETTS  
GENERAL HOSPITAL

---

### THE SURGICAL MENOPAUSE

#### INTRODUCTION

In this discussion of the menopause all means of bringing it about artificially will be considered. Since the physiological menopause is due to primary ovarian failure, it is only by removal or destruction of the ovaries that it can be produced artificially. Diseases of the pituitary gland which may be responsible for a permanent amenorrhea and secondary ovarian failure are not included except where comparisons with this type of "menopause" are necessary. Debilitating disease and lack of ovarian development are also omitted. By the surgical menopause is meant a permanent amenorrhea accompanied by the signs and symptoms of the climacteric brought about artificially by three means only: radium, roentgen therapy and surgery.

#### RADIUM

That the radiologic destruction of the ovaries is permanent in some cases is not questioned, but in some instances, although amenorrhea may be present for a time, the ovary may merely be in a state of lowered activity and in time may become re-activated. This has already been shown in many instances by the return of the catamenia after radiation castration.

In young patients greater difficulty is found in bringing about a permanent cessation of menstruation than in older women nearer their climacteric or menopause. The use of radium to cause a cessation of abnormal bleeding in older

women is an excellent practice, at least so far as it can be judged at this time. That there is a distinct danger in the use of intra-uterine radium cannot be doubted, and the development of carcinoma of the endometrium in a recent patient treated eleven years before brings considerable thought to the problem of the later development of cancer in such individuals. The frequent occurrence of cancer on the site of a radium or roentgen ray burn must not be forgotten, and in any patient who has recurring bleeding following radium treatment the possibility must be considered. Young women are usually given very small doses of radium for the purpose of checking ovarian function without destroying it. Such doses usually vary from 200 to 600 millicurie hours. This dosage in all likelihood will not cause a permanent cessation of menstruation, and in from two months to two years the patient's catamenia will recommence. In older patients the dosage that is considered to be large enough to produce an artificial menopause is 600 to 2500 millicurie hours. In most instances the result is satisfactory; flowing ceases and menopause symptoms occur. However, even in some cases that have been given large doses menstruation has recurred and the menopause has not been permanently secured. It is in these cases that the possibility of malignant disease must be considered, for if the treatment is unsuccessful the presence of an overlooked tumor is a possibility; the chance of a granulosal cell tumor of the ovary is always present, and the definite possibility of a neoplasm starting in the radium reaction must be kept always in mind.

#### ROENTGEN RAY

Some surgeons, gynecologists, and radiologists prefer to use the roentgen ray as a means of establishing the menopause in patients who are bleeding or who have fibroids with abnormal catamenia, or in patients where the physician feels that the long drawn-out premenopause symptoms would cease by bringing about the true menopause.

In young women the roentgen ray is used in small doses to cause a cessation of abnormal flowing in the same way that

radium is used, but here again the chances are that a permanent cessation will not be brought about. Nevertheless, it has happened that in patients with low ovarian function (and it is in these that abnormal bleeding is often present) a permanent cessation of menstruation has occurred and the menopause has been created. This is sometimes very tragic, for the menopause is not a healthy state for the young because of the secondary changes that are brought about in the patient's genital tract. Avoidance of the menopause in youth should always be the rule. In older women with abnormal bleeding and with fibroids and other reasons for causing a cessation of flowing, roentgen ray therapy is very satisfactory. However, the practice of thus treating abnormal bleeding or fibroids without preliminary curettage and investigation of the endometrial cavity is to be deplored. This is a dangerous method, for large polyps, carcinoma, sarcoma, and other pathological conditions are often overlooked. It has been the author's misfortune to see a number of examples of this poorly conceived type of treatment; women who otherwise would have had a chance for life have been maltreated and all hope of cure has been taken from them. Cancer of the endocervix and body of the uterus often cannot be discovered by bimanual examination, and in these cases the employment of roentgen ray therapy without curettage to cause a cessation of bleeding and bring about the menopause is inexcusable. The amount of treatment given to produce the artificial menopause is well standardized by all roentgenologists, so that it is not necessary in this paper to go into the type and amount of treatment to be given.

#### SURGERY

The safest way of producing the menopause is the surgical method, for here the uterus and the ovaries can be removed, whereas in the radium and roentgen ray menopause they are left behind in a definitely damaged state. Ovarian pathology that might be overlooked in radiation treatment can easily be removed by surgical methods, and the patient cured. The removal of all ovarian tissue in young girls when the ovaries are

not pathologic is a great tragedy, and certainly they ought not to be removed unless diseased, in any woman under the age of forty-five. Most hysterectomies are done for abnormal bleeding or fibroids; it is not necessary in most instances to remove the ovaries in order to accomplish the purpose of the operation, and conservatism as regards this operation is highly advisable. If the ovaries are removed the uterus usually should be removed also, for the uterus without the ovaries acts almost like a foreign body. It is safer to get rid of this organ if it contains fibroids or polyps, for an organ that can grow one sort of neoplasm can also grow another of a more serious type. In older women when one is operating for fibroids, polyps, bleeding, or cancer it is wise to remove the ovaries, for they are already atrophied or abnormal and of no use in the body physiology, and the operation of hysterectomy is easier when the ovaries are removed than when they are conserved. Furthermore, such ovaries in cancer are often the seat of metastases, and it is sometimes impossible in gross to determine whether such a metastasis is present or not. In the case of women between forty and fifty, younger than the climacteric age, the question of removal of the ovaries is more difficult, but it is a safe rule to remove them if there is any evidence of pathology, and to leave them if they appear normal. The menopause should be avoided if possible because of its disagreeable symptoms and manifestations.

#### SYMPTOMATOLOGY

The menopause, as we have mentioned, is due to primary ovarian failure, and with such failure comes a chain of symptoms and of signs that are far from agreeable. The menopause is most frequently characterized as the time of hot flashes or flushes. This phenomenon may start in the face, or all over the body, or may begin in an extremity and rush to the face. There is a sense of suffocation and of great heat, and frequently the patient tries to get near an open window or door, or uses a fan. She is greatly concerned for fear her red face will expose her to the comments of her friends, but it is not

very frequent that this state is recognized, even by intimates. The flash, or flush, is similar to a blush, and it lasts a comparatively short time. This phenomenon is, however, a very frequent one, and often a patient may have from 1 to 30 per day. It is common for rest and sleep to be disturbed by periods of flushing that cause the patient to wake in a drenching perspiration. It is often necessary for the affected woman to change her nightgown two to four times a night. This may greatly disturb the night's rest and affects the performance of her daily duties. Hot flashes are but a part of her difficulty, however, and general nervous trends are well recognized; irritability is present and even serious nervous disorders can ensue, such as depressions, loneliness, lack of confidence, irritability, and even melancholia.

The physical characteristics also change in some instances, though not in all. It is not unusual to see the face become gross, the body heavy, and a certain amount of hair develop on the lip and chin. A moderate masculinization occurs in quite a few cases, but in some a more marked change toward the male type is seen. In others, however, femininity predominates; no one can fail to recall many old ladies of the most feminine types, yet these women have had a menopause for a number of years. Obesity also occurs, but may be due to a change in eating habits rather than to any change in the pituitary or other endocrine glands. Many old ladies are slender and fragile, and obesity and grossness are not always typical of the menopause.

Physiologically also there may be a change. A very feminine person may become dominant and commanding, and may assume definite male characteristics in her reactions to life. The libido may cease, but in some instances it shows a definite increase. Occasionally a woman may lose all interest in the opposite sex, only to be intrigued by her own. These, however, are the unusual and almost pathologic signs of the menopause. Certainly as we look about and see the numbers of older women well past the menopause who are living more contentedly than ever before we hesitate to classify the few

acquaintances who have signs of grossness and masculinity as normal older women. Some women who have suffered all their lives from dysmenorrhea, from the fear of childbirth, and from excessive flowing are completely made over by the climacteric, and look upon it as a relief from the dreads of younger years. These women bloom during the change, and live lives of great pleasure, having thoughts and ideas never before possible to them. Too much has been written about the ugly side of the menopause and too little about the great possibility of a more perfect and happier life. Just as before the menopause there are feminine and masculine women, retiring and aggressive women, weak and strong women, so after it the same contrasting types are found; the few instances of definitely pathologic changes are usually taken for the normal climacteric, so that a legend has been built up that terrifies all women who hear of it.

#### PATHOLOGY

In the radium or roentgen ray menopause certain changes take place in the ovaries that should be recorded here. These two organs atrophy, primordial follicles disappear, graafian follicles fail to form, and the entire ovary becomes fibrous. Even the interstitial cells and active stroma so evident in all ovarian tissue vanish, and all that is left is a tough, white, wrinkled ovary with an occasional cystic area surrounded by tough, hyalin-like connective tissue.

In the artificial menopause of any type the breasts atrophy, the epithelium that is usually stimulated by the ovarian hormones becomes inactive, and throughout the gland connective tissue is predominant. The breasts become smaller and firmer in the sense of being homogeneous and tough, and are often pendulous without the usual soft fulness. The uterus atrophies markedly and resembles the juvenile uterus, the length of the body approximating that of the cervix. There is but little muscular structure left, and the proportion of connective tissue is increased. The endometrium atrophies and in many instances but one layer of epithelium, either cuboidal or columnar, lines the cavity. Occasionally the endometrium retains a

structure, but the glands are often parallel to the musculature and not perpendicular as in the active sex life.

The cervix becomes more conical and pointed, and the external and internal ora are much diminished in size. Often the os may partially close, thus causing a pyometrium as the cervical cicatrix prohibits secretion from escaping. The epithelium is continuously desquamating, and eventually this cast-off tissue becomes softened and infected and a pyometrium develops. The vagina atrophies and the mucous membrane is often red and infected. This is due to the fact that the tissue of the vagina cannot resist moderate infection which adult tissue prior to the menopause would be able to resist. Frequently adhesions are formed owing to excoriated areas of mucous membrane sticking together. The possibility has long been considered that cicatrices of the vagina and cervix with the damming back of secretions are responsible for the development of carcinoma of the cervix or body of the uterus.

The vulva changes in appearance. It loses its softness and vascularity, becoming thinned out. The labia minora are obliterated, and sometimes even remnants of them are hard to find. It is in this stage of vulval atrophy that leukoplakic changes occur and the skin is thin and white, with the underlying tissues tough and close to the surface. Following the development of a true leukoplakic vulvitis, kraurosis or parchment-like whitening of the vulva takes place.

The urethra is frequently involved in the atrophy, and the tube contracts in such a way that normal voiding is impossible. As a consequence of this cystitis develops, and to clear up the frequency, urgency, and difficulty of emptying the bladder dilatation of the urethra is necessary.

The anus also shares in the marked atrophy and this may be responsible for very difficult constipation, which necessitates stretching or incision of the sphincter ani to bring about relief.

Except for the pituitary it is necessary to guess concerning the pathology of the other glands of internal secretions. The former gland apparently hypertrophies and oversecretes the gonadotropic hormone, prolactin A. It should follow that the

other glands overact on account of this hypertrophy, but it is well known that myxedema, or at least lowered rates of thyroid activity, follow upon the menopause rather than hyperthyroidism, which is not common. It is possible also that the adrenal may secrete less than formerly, although this is pure speculation. The hot flashes of the menopause may be due to an overstimulation of the adrenal with consequent hypersecretion of adrenals, and thus be partly responsible for the vasomotor phenomena. It is reasonable to assume that the masculinization seen in the menopause is due to oversecretion of the hormone of the adrenal cortex, which in neoplasms of that organ causes such severe changes to the masculine side. It is more likely, however, that after a temporary hypertrophy of the pituitary the gland secretes less and less of the thyrotropic and adrenotropic hormones.

Hypertension of the malignant type or of the milder type is often present at the time of the menopause but lack of estrin (theelin) or increase of prolan A has not yet been established as the real etiology. It is true that hypertension does occur at this time, but whether it is entirely due to failing ovarian function is not quite certain.

#### BIOLOGIC CONSIDERATIONS

In studying the menopause in the ovarian dysfunction clinic of the Massachusetts General Hospital, Albright has attempted to show in a series of papers what happens to the two hormones that can be assayed. There is an absence of estrin (theelin) in the true menopause, and there should be, for without the ovary no estrin is secreted. The prolan of the follicle-stimulating type of the anterior pituitary increases in amount. It is very probable that there is prolan present in every menstruating woman, but it is apparently not great enough to be found with the method of extraction employed in Albright's laboratory. It was noted in his experiments that the symptoms of the menopause do not follow directly upon the absence of estrin, for after surgical removal of the ovaries the estrin is at once negative, yet flashes do not occur for two

weeks to a month later. It was also noted that when estrin made its appearance in the urine following administration of the hormone as treatment the number of hot flashes did not diminish until the prolactin content was reduced or completely removed. It is also apparent that hot flashes fluctuate in numbers and that the fluctuation is in some way connected with the fluctuation of the amount of prolactin A in the urine and not related to estrin. For these reasons he suggests that prolactin A is in some way connected with the occurrence of hot flashes rather than lack of estrin.

Simple amenorrhea does not necessarily mean the menopause, for in various studies it was found that when no prolactin A and no estrin were present hot flashes were not a part of the picture. It is therefore evident that such a type of amenorrhea, which might be confused with the menopause, is due to a secondary ovarian failure, to a primary failure of the follicle-stimulating hormone (prolactin A) of the pituitary. Such patients may have a normal ovary capable of secreting estrin, but the pituitary, its governor, does not stimulate it to do so. One is able to differentiate the type of amenorrhea by a study of the twenty-four-hour specimen of urine and of the first morning specimen. When a given patient has no prolactin A and a normal estrin pattern she is considered in a normal state.

Chart 1 gives the various patterns of the three types of cases under discussion: the normal, the secondary ovarian or pituitary failure, and the primary ovarian failure.

CHART 1

	Prolactin A	Estrin
Normal	0	+
Pituitary failure	0	0
Ovarian failure	+	0

From the chart one should be able in most instances, after a careful assay of the urine, to determine the class into which a patient fits.

#### TREATMENT

In treating patients with the menopause it is necessary to do only two things: to bring estrin back into the urine, and

to reduce the amount of prolan A present. Some patients are very resistant to treatment and it is necessary to give large amounts of estrin to bring about the desired result. It is reasonable to assume that the estrin given by mouth acts as an inhibitor of the pituitary and thus less prolan A is manufactured, and if prolan A is in any way responsible for hot flashes its diminution should lessen their number.

It is better in treating patients suffering from nervousness, irritability and hot flashes to give estrin in effective amounts at the onset than to give small amounts and build up to an effective dose. This is so because such patients are skeptical of treatment, and if such treatment is a failure in the first week or two it is often difficult to persuade the patient to continue. Therefore, the method of treatment should be to give large doses at first and then cut down as necessary. That the treatment is expensive there can be no doubt, but once a proper dosage is established it can be cut down slowly to an amount the patient can afford. There is no doubt that given satisfactorily this treatment is eminently successful. Two injections of 50,000 international units per week should suffice, but an easier method of treatment is to give estrin by mouth. In the ovarian dysfunction clinic, progynon has been used with great success, and this has been carried on just as well in private practice. The method used by the author is to start a patient on two 600 rat unit tablets of progynon each day, and after a week, if no relief has been obtained, to raise it to 3, or to 4 or 5. After relief has been experienced the amount is cut down to 1 per day, 1 every other day, 1 every third day; then 200 rat unit tablets, 1 a day, 1 every other day, 1 every third day; and then to 45 rat unit tablets, 2 per day, 1 per day, and 1 every other day, or whatever dose will keep the patient comfortable. There is no doubt that nearly all hot flashes can be stopped, but to make a patient comfortable it may be necessary only to *reduce* them, and not to stop them entirely. The only measure for the proper dose is the comfort of the patient.

It is interesting that estrin given subcutaneously, by mouth.

or by means of vaginal suppositories relieves and improves the senile vaginitis experienced by menopause patients. Many of these women, complaining as they do of pruritus vulvae, are also relieved to a great extent by the use of estrin either subcutaneously, by mouth, or by suppository (more often by suppository than by either of the other two methods). The treatment can be followed by frequent vaginal smears, the presence of large squamous epithelial cells with nuclei, with or without pus cells, determining that a satisfactory change has taken place. This observation can be easily made in the office by removing a drop of discharge, placing a drop of water upon it, and examining it, unstained, under the high power of the microscope with the light cut partly down. Once the physician knows that the cells have changed, he will be able to assure the patient that her itch and discharge will presently clear. All cases of pruritus vulvae are not cured in this manner, but those due to vaginal discharge of the senile type are in many instances relieved of their symptoms.

Hormone treatment of the menopause is not the only method of helping these unfortunate patients. The use of carefully planned sedatives to assure them sleep at night, and thus enable them to handle their daily problems, is of great value. Sleeplessness coupled with nervousness, irritability, and so forth, is such a bad combination that if it can be broken up and the patient freed of at least some part of her symptoms, great relief can be expected.

The use of very strong iodine in the vagina with the patient anesthetized helps in great measure to cure the terrific senile vaginitis and disagreeable pruritus.

#### CONSERVATION OF THE OVARIES

In any discussion of the menopause, mention must be made of the fact that many surgeons and gynecologists think that the symptoms are no worse after the removal of both ovaries than after conservation of one or both of them. It has been my privilege to observe both schools of thought in this regard. Although no figures directly applicable to this argument are

available continued observation of both types of cases has led me to conserve one or both ovaries whenever possible when doing a hysterectomy on patients under the age of forty-five. It is felt by some that it is even more satisfactory to leave in a part of the endometrium so that a normal amount of menstruation may continue to occur, but this has not been my experience; the effect of such small bleeding is to cause constant worry and distress to the patient. In many instances it has been necessary to remove the retained cervix and its accompanying endometrium so as to put the patient mentally at rest. Figures that can be made to prove everything are available in the literature concerning hot flashes and ovarian conservation, so that it is an easy matter to advance any procedure and prove it as best for the patient. My own opinion is that in doing a hysterectomy in a young person up to forty-five years of age, conservation should always be practiced; that from the ages of forty-five to fifty it should be practiced if the ovaries appear normal to the individual operator; and that after fifty or after the menopause has occurred it makes no difference. Yet there are others who differ from this opinion and say that even in the atrophic state the ovary has a function, and that after removal of such ovaries patients show a definite lack of some factor that was important to them.

In an endeavor to determine how long the conserved ovary or ovaries of young people hold off the menopause, a study was made of 10 patients operated upon five years previously, the women at that time being less than forty years of age. Prolan A determinations were made four months apart on these patients five years or more after operation. Prolan A is rarely found in a normal individual, and if it were positive on two occasions this was taken as proof of at least the increased pituitary function that is found so commonly at the menopause. If this finding were also accompanied by a symptomatic menopause (hot flashes, etc.) then it could be concluded that the menopause had taken place. If, on the other hand, prolan A was negative—and it rarely is in a patient who has had the menopause—on two occasions four months

apart, and if the patient had no symptoms of the menopause, we might conclude that it has not been reached, in spite of the fact that the uterus, and in some cases one ovary, had been removed.

The results were quite striking. Three patients on both occasions had positive prolan A determinations and symptoms of the menopause, whereas 7 had two negative prolan A tests and no symptoms of the menopause. This small study is open to severe criticism on the ground that estrin determinations were not made, but it was so difficult to obtain twenty-four-hour urines for these determinations that it was decided that the presence or absence of prolan A and the presence or absence of symptoms of the menopause would have to suffice to allow deductions. There was no common factor in the series, either in age or total or supravaginal hysterectomy, but all the patients who had the menopause had only one ovary left in. On the other hand, only 3 of 8 cases with one ovary left in had developed the menopause.

It was therefore deduced from this study that the proper procedure in order to avoid menopause symptoms is to conserve as much ovarian tissue as possible and to protect the blood supply of the ovary carefully; this implies that the tube is not to be removed unless necessary, and that if it is removed it must be taken off at the tubal side of the mesosalpinx in order to preserve the back-and-forth anastomosis of blood vessels in the mesosalpinx. The ovary should be allowed to stay high in the pelvis, special effort being made to keep the infundibulopelvic ligament with the ovarian vessel in it loose and free from tension. The practice of tying the round ligament and the ovarian vessels together and attaching them to the top of the cervix or vagina is considered an unsatisfactory method of preserving a proper blood supply for the ovary.

#### CONCLUSIONS

- 1 The menopause is a phenomenon of primary ovarian failure
- 2 It has far-reaching physiologic, psychic, and physical effects

3. Its presenting symptoms are usually those of hot flashes and increased nervousness and tension.

4. It is probably connected with increased prolan A rather than decreased estrin.

5. Its relief is effected by means of sedatives plus treatment with estrin (theelin) either by mouth, subcutaneously, or by suppository.

6. Whenever possible the surgical menopause should be avoided in youth, and conservation of ovarian tissue ought always to be practiced.

7. Proper conservation means an anatomical consideration of the blood supply of the ovary. The tube should be removed as far away from the ovary as possible and there should be no tension on the infundibulopelvic ligament.

8. In at least 7 out of 10 patients operated before the age of forty conservation was successful in preventing menopause symptoms and prolan A was absent in two urine specimens five years later.

## CLINIC OF DR. TRACY J. PUTNAM

FROM THE NEUROLOGICAL UNIT, BOSTON CITY HOSPITAL AND  
THE DEPARTMENT OF NEUROLOGY, HARVARD MEDICAL SCHOOL

---

### THE DIAGNOSIS OF MULTIPLE SCLEROSIS AND THE OUTLOOK FOR TREATMENT\*

**Introduction.**—Multiple sclerosis is in many respects a peculiar disease. The symptomatology is protean and while there are several characteristic syndromes, a large proportion of cases fail to correspond to any of them, especially in the early stages. The "Charcot triad" may be so closely imitated by other diseases that a differentiation can only be made by autopsy. The *course* of the disease is irregular and unpredictable. The result of this diagnostic uncertainty is reflected in any attempts at a statistical study of etiology, prognosis and treatment.

The one secure starting point for any discussion of multiple sclerosis is its pathological anatomy. Nothing else can give us as clear an idea of what kind of a disease it really is. Fortunately, recent work has tended to simplify rather than to complicate the subject.

**Pathology in Relation to Symptomatology.**—The characteristic anatomical change in multiple sclerosis is the occurrence of numerous scars scattered throughout the central nervous system. Indeed, by the time death occurs it may be difficult to find any part of the brain or cord which is entirely normal (Hassin<sup>1</sup>). There are certain areas of predilection; the optic nerves, the periventricular region, and the pons are almost invariably affected. The scars are of various ages, and

\* This is the eleventh of a series of articles, based largely on investigative work financed by the Multiple Sclerosis Fund of Harvard University.

there is nothing unique about the process of healing, the rather complicated details of which need not concern us here. What is of clinical importance is, first that lesions showing every evidence of recent origin (edema, myelin in the early stages of breakdown, perivascular infiltration with glial cells) occur

Fig. 35.—Plaque from the cerebral white matter of an old case of multiple sclerosis. The center of the demyelinated area is composed of firm fibrous glial tissue. The edges contain myelin fragments in the process of breakdown, and an acute glial reaction with perivascular infiltration. Mason stain,  $\times 15$ .

in practically every case, about the edge of or adjacent to old fibrous scars (Fig. 35). Second, these fresher lesions go through a stage of acute edema before settling down to a relatively fixed state. And third, that extensive and obviously irreparable changes are found not only in the myelin but in the axis-cylinders of most plaques (Fig. 36). The extent of the

loss is indicated by a recent study of 35 plaques from 11 cases. Axis-cylinders were found practically absent in 18 of the lesions, and greatly reduced in 13.

The practical significance of these facts is obvious. First, because lesions are always multiple, the diagnosis is always

FIG. 56. The same plaque, stained for axis-cylinders. They are practically absent in the center of the lesion. Section from the same block as that shown in Fig. 55. Davenport stain,  $\times 15$ .

open to question unless symptoms or neurological examination discloses evidence of more than one lesion. Obviously, the symptoms may be extremely varied, and there is no predicting the rate or order in which they may occur. In general, however, there is a tendency to exacerbation or recurrence of already existing symptoms. Second, we should expect most symptoms to undergo spontaneous improvement of greater or

less degree, and again, the picture as a whole must be unusually characteristic to justify an absolute diagnosis if no remissions have occurred. Third, symptoms of long standing are usually permanent. More will be said below concerning pathology in its relationship to etiology, prognosis and treatment.

From a purely clinical point of view, perhaps the soundest way of giving a rapid survey of the possible manifestations of multiple sclerosis is to refer to the tabulation, which is taken

### TABULATION

TOTAL NUMBER OF CASES STUDIED 141 (MALE CASES 77, FEMALE 64)  
SYMPTOMS AND SIGNS ENUMERATED IN THE ORDER OF THE FREQUENCY OF THEIR OCCURRENCE\*

	Cases	Per cent
1. Abdominal wall reflexes were markedly diminished or absent in . . .	118	83.7
2. The chief complaint was weakness and stiffness of one or both lower extremities	115	81.7
3. Nystagmus was present in	99	70.0
It was chiefly horizontal.		
Horizontal and vertical in	17	12.0
Horizontal and rotary in	3	2.0
4. Babinski's sign was present bilaterally in	94	67.0
Unilaterally in . . . . .	16	11.3
5. Tremor was present in the extremities alone in	78	55.3
There was also tremor of the head in	31	22.0
6. Ataxia and adiadokokinesis were present in .	66	47.0
7. Deep reflexes in the lower extremities were increased in	126	90.0
Ankle clonus was present in . . .	61	43.0
Patellar clonus was present in	29	20.5
In 3 instances the knee jerks were diminished (tabetic type).		
8. There was a history of 1 or more remissions in	59	42.0
9. There were bladder symptoms in	57	40.0
Urgency was present in	18	12.6
Delay in starting urinary stream alone or in combination with urgency in 28 cases and incontinence in 21 cases.		
10. Speech was hesitant or otherwise disturbed in	51	36.0

# THE DIAGNOSIS OF MULTIPLE SCLEROSIS

581

	Cases	Per cent
11. The gait was spastic in .....	43	30.0
Spastic ataxic in .....	46	32.6
Ataxic alone in .....	15	10.6
12. There was evidence of facial weakness in .....	46	32.6
The other cranial nerves were very much less involved.		
The tongue deviated to the right in .....	14	10.0
There was difficulty in swallowing in .....	5	3.5
Uvula was drawn to one side in .....	4	2.8
The cochlear nerve was involved in .....	3	2.0
The vestibular nerve showed no response to stimulation in .....	2	1.4
Of the ocular muscles the internal rectus was involved in .....	6	4.3
There was ptosis in .....	2	1.4
The external rectus was involved in .....	3	2.8
13. Temporal atrophy was noted in .....	46	32.6
There was blurring of the disks or mild optic neuritis in .....	11	7.8
Vision was impaired without objective disk findings in .....	25	17.7
14. Pain, numbness and tingling were noted in .....	43	30.0
Objective disturbances in posterior column sensation were present in .....	24	17.0
Mild changes in pain, temperature and touch perception were noted in .....	23	16.3
(Among these were cases with hyperalgesic zones.)		
Astereognosis was noted in .....	5	3.5
15. There was a history of diplopia in .....	31	29.0
16. Cremasteric reflexes were diminished in .....	17	22.0
(Of the males cases.)		
17. Mental changes were noted in .....	22	15.8
They were largely those of mental infantilism and signs of neurosis or neurasthenia. One patient was in a state hospital with the diagnosis of dementia praecox. One patient showed the picture of Korsakoff's psychosis		
18. Emotional instability with explosive laughter occurred in .....	24	17.0
Defects of memory occurred in .....	7	5.0
19. Spinal tenderness was present in .....	17	12.0
It was chiefly midsacral.		
There was a history of trauma in .....	14	10.0
20. Papillary disturbances were noted rarely.		
Papillae were irregular in .....	6	4.3
They were slightly sluggish to light in .....	12	8.5
Atrophy was present in .....	16	11.3
21. There was a history of marked dizziness in .....	12	8.5
22. Incontinence of urine was noted in .....	6	4.3
No disturbances in rectal control were seen in any of our cases		

from Sachs and Friedman.<sup>2</sup> The signs and symptoms tabulated occur in almost every conceivable combination. Symptoms not given in Sachs and Friedman's table, but which have been observed in cases of multiple sclerosis in this clinic, include convulsions, paralysis agitans, trigeminal neuralgia and other "neuralgic" pains, muscular atrophies, and oscillopsia.<sup>3</sup> Mild leukocytosis and fever are common.<sup>4</sup> Stubborn constipation may be a most annoying symptom.

A characteristic phenomenon is the transient first symptom—often little noticed, and only recalled by effort on the patient's part. In a recent survey, Dr. Madelaine Brown found that 32 of 52 undoubted cases observed at this clinic gave a history of such a temporary manifestation at the onset. Numbness or weakness of one extremity or staggering were the commonest early symptoms, but diplopia and retrobulbar neuritis made up an important fraction of the group.

The age incidence of multiple sclerosis has been given by von Hoesslin<sup>5</sup> as follows: 1.4 per cent (of 516 cases) began before the age of ten years; 68.8 per cent between twenty and forty; 4 per cent after fifty. There have been reported instances of more than one case in a family, and I have seen two pairs of sisters so affected. The possibility of a mistake in diagnosis from the hereditary ataxias is, however, a real one (Mackay and Hall<sup>6</sup>).

**Precipitating Factors.**—The onset of multiple sclerosis, and the occurrence of exacerbations are not preceded by any unusual event in the majority of instances. The new symptom may develop so insidiously that it is impossible to date it, but about as often, the patient can say that it began at a certain hour. Occasionally, attacks are "apoplectiform." In a minority of cases, the disease begins or is grossly exacerbated by exogenous factors. Von Hoesslin found about 30 per cent of such cases among 516 records which he studied personally, and lists the factors as on page 583.

I have been greatly struck by the influence of pregnancy and menstruation on the course of the disease. One woman (in whom the diagnosis was confirmed by autopsy) began to

	Per cent
Injury and accident . . . . .	11.4
Pregnancy and labor . . . . .	5.8
Febrile diseases . . . . .	4.2
Overexertion . . . . .	3.9
Chilling . . . . .	2.3
Fright and emotion . . . . .	2.0
Poisoning . . . . .	0.5

have irregular menstrual periods toward the end of her course. Preceding each one she would have a two days' fever, and become completely paralyzed, often unconscious. Each of these events marked a step downward in the progress of her disease, which was practically stationary between them. I do not remember any female patient with multiple sclerosis who has gone through several pregnancies without an exacerbation.

**The Spinal Fluid.**—Examination of the spinal fluid is the only laboratory examination of great positive value in the diagnosis of multiple sclerosis. The following data, based upon 1068 cases, is borrowed from Merritt's article.<sup>7</sup> The cells were found to be increased (taking 5 as the upper limit of normal) in 28 per cent of cases. An abnormal amount of "globulin," as measured by qualitative tests such as the Pandy or Ross-Jones, was found in 45 per cent. Quantitative determination of protein revealed an increase above the normal in 24 per cent of the cases examined. Abnormal gold-sol curves were found in 71 per cent of fluids examined, a *first zone curve* being the type most frequently found. A slight increase of pressure is occasionally reported. In only 17 per cent of cases was the fluid entirely normal. On the whole, increase of cells or protein occurs slightly more often in cases showing progression than in those that are stationary.

Exacerbations occasionally appear to be precipitated by lumbar puncture, which should therefore only be performed when a real diagnostic indication exists. The effect is probably not to be ascribed to drainage of fluid, for I have seen similar reactions following venepuncture and other minor procedures. They are probably mediated by emotional disturbances.

It is the exception rather than the rule that the diagnosis of multiple sclerosis can be made positively on the basis of typical manifestations. More often it is made by the exclusion of such conditions as tumor of the brain stem or cord, neurosyphilis, syringomyelia, and combined system disease. An especial difficulty may be encountered in the diagnosis from the hereditary ataxias (Mackay and Hall<sup>6</sup>). In this group of diseases, the symptoms of multiple sclerosis may be imitated so closely as to deceive the very elect. The occurrence of other cases of organic nervous disease in the same family, the chronic course without remissions, and the absence of the characteristic spinal fluid picture are aids in diagnosis.

I shall make no attempt to set up criteria of differential diagnosis from disseminated encephalomyelitis, diffuse sclerosis, and neuroptic myelitis. It appears probable that these diseases represent variants of the same fundamental disease process, and transitional forms between the various groups occur.<sup>8</sup>

**Course and Prognosis.**—The usual current impression of multiple sclerosis is that it is a disease of relentless progression, bringing early and prolonged helplessness. Such cases do occur, and it is difficult to find a more tragic group in all of medicine. Of the 53 patients followed four years or longer by Dr. Brown, 11 are dead, 21 were helpless when last seen, or if dead, had been helpless for periods up to twelve years. It is common for a patient to survive three years after becoming bedridden, but rare for him to survive over six.

This is not the only possible outcome, however. Three of the patients who had at one time presented an unmistakable picture of multiple sclerosis, considered themselves perfectly well. Nineteen others were still ambulatory, and some of them at work. Remissions up to twenty years in length are recorded by von Hoesslin<sup>5</sup> and one of his patients survived the first symptom by fifty-one years.

The severity of the early symptoms appears to have little bearing on the ultimate prognosis. Thus, a patient who ten years ago was completely paralyzed in all extremities, with

various cranial nerve palsies so that he had to be tube fed. has since recovered except for a slight limp and is earning a living. On the other hand, sudden, fatal exacerbations may occur in the course of a chronic progressive case.

**The Problem of Etiology.**—All that has been said so far concerning multiple sclerosis is a matter of well-documented

FIG. 57.—Thrombus from the edge of a plaque in an old case of multiple sclerosis, in which death occurred during an exacerbation. Endothelial cells are invading an amorphous mass of platelets. A tangle of fibrin is seen in the right hand side of the lumen. Masson stain, oil immersion.

observation, to which few neurologists can take exception. When we come to the question of etiology, and thence to that of treatment, unanimity vanishes. A large number of divergent, often mutually exclusive guesses have been made in regard to the essential nature of multiple sclerosis. They have recently been well reviewed by Brain<sup>9</sup> and by Brickner.<sup>10</sup> It is to my mind a tedious waste of time to enumerate them again,

and to assemble the arguments which are held to support or confute them. I shall merely present an outline of the point of view which has gradually forced itself upon the workers in this laboratory who have occupied themselves with the subject for the past eight years; but before doing so, I feel I should warn my readers that these views are bitterly opposed by some authorities who have committed themselves to other opinions.

All of the data which have been collected by the group who have collaborated under the Multiple Sclerosis Fund has pointed to thrombosis of capillaries and venules as the origin of sclerotic plaques. Such thrombi (Fig. 37) have often been observed in various organs of the body in autopsies of patients dying from infectious diseases, certain forms of poisoning and without obvious cause. They have been produced experimentally by Kusama<sup>11</sup> and others by injections of homologous serum and other proteins, tissue extracts, suspensions of dead bacteria, bacterial filtrates, colloids, ether and metallic poisons. They occur frequently in allergic lesions. In cases of multiple sclerosis,<sup>12</sup> of some forms of encephalitis, and of carbon monoxide and nitrous oxide poisoning, they occur not only in the vicinity of the cerebral lesions but diffusely throughout the body.<sup>13</sup>

The relationship of the plaques to the thrombi is shown by the fact that all of the characteristics of the sclerotic plaque (including the so-called "inflammatory" phenomena) may be produced experimentally in animals by venular obstruction<sup>14</sup> and may also be observed in human pathology as a result of venous (more rarely arterial) obstruction of any origin.<sup>15</sup> Confirmatory evidence has been secured by the special methods of micro-incineration<sup>16</sup> and by a demonstration of abnormalities of vascular architecture.<sup>17</sup>

A comparison of the list of apparent precipitating factors given above will show that it corresponds closely with a list of factors accelerating the clotting of blood. Simon and Solomon have shown that there is a lability of coagulation time in many patients with multiple sclerosis.<sup>18</sup>

**Criteria of Treatment.**—If the hypothesis of the nature of multiple sclerosis just outlined can be accepted, it would seem *a priori* unlikely that any of the methods of treatment so far proposed should be particularly effective, and it has been my experience that none of them are. I have seen a large number of patients treated in this community and elsewhere with antiseptics such as the arsenicals and antimonials, forced spinal drainage, resection of the sympathetics, administration of autogenous vaccines, quinine, artificial fever, and vitamin therapy without being led to believe that any of the procedures have produced a change for the better in the course of the disease. Some of them clearly produced a change for the worse. To be sure, the proponents of each form of treatment report a certain proportion of successes, but the frequent occurrence of remissions makes their evaluation difficult. The tendency to euphoria and naïvety which so often accompanies the disease increases the difficulty.

Is it, then, hopeless to establish any criteria of the success of treatment? Certainly not. The accepted, obvious facts of pathology lay down certain limitations. As we have already seen, the formation of the lesion goes through two stages. The first is that of parenchymal damage or destruction, and there is every evidence that this is ordinarily a brief process. Then there is a stage of recovery of the less damaged tissue elements, and reparatory gliosis—a process extending over months or years.

*It is impossible to conceive that any treatment whatever can grow new axons in the central nervous system, and hard to imagine that the recovery of damaged axons can be accelerated (unless possibly by improving faulty nutrition). The success of a given treatment should be judged not on the basis of its effect on existing symptoms, but on its success in preventing relapses. I know of no treatment that does this.*

To be sure, the available statistics of the occurrence of remissions and relapses are wholly inadequate. To remedy this situation, Dr. Richard Brickner of New York has been instrumental in having a special commission appointed by the

American Neurological Association to study the subject, by reporting on groups of cases carefully observed, over a period of five years, under various forms of treatment.<sup>18</sup> A control series of 52 patients who have received no systematic treatment has been observed by Dr. Madelaine Brown at this clinic. While the investigation is still incomplete, and represents only a fragment of the study, some facts of interest may be gleaned from it. One is that in about 60 per cent of the cases, the initial symptom disappeared spontaneously. This comes very close to the proportion of favorable cases reported improved by practically any method of treatment (Brickner<sup>19</sup>), and it is all the more striking because the group contains many wholly unfavorable cases, in which the disease necessitated confinement to a hospital for chronic diseases or asylum almost from the onset. Three of these patients considered themselves well, and 12 were working. These figures also come close to the most favorable reports of the effects of treatment.

**What Help Can We Give to a Patient with Multiple Sclerosis?**—The fact that no satisfactory specific treatment for multiple sclerosis has yet been established does not mean that nothing can be done for patients suffering from the disease. At many points, the doctor's attitude and advice may make the difference between comfort and misery.

In the first place, the problem always comes up whether and when to announce the diagnosis to the patient. This is a matter of personal policy for every physician to decide in each individual case. My own point of view is that the situation must eventually be faced, and that it is usually better to have the depression which is often precipitated by the disclosure at a time when there is still hope that improvement may occur to mitigate it. The blow may be softened by pointing out that multiple sclerosis is by no means such an invariably hopeless disease as is sometimes stated, that more has been learned about the cause of the disease in the last decade than in all the rest of the century since it was first described, and that there is some reason for believing that an effective treatment may be found before many more years are over.

The real advantage of this candor lies in the fact that the patient may then often be saved the time, trouble, expense, and much greater aggregate disappointment which results from going from one enthusiastic therapist to another.

A careful survey of the patient's general health and hygiene should never be omitted. Of particular importance is a search for foci of infection, especially tonsils, teeth and sinuses. Anemia may be present, and should be corrected. The patient should have a diet which is on the meager side, and should avoid adiposity. Exercise within his strength is to be recommended. I have seen no advantage from prolonged rest in bed for patients able to be about. In female patients, pregnancy is to be avoided. It is my impression that most sufferers from multiple sclerosis do best in a warm, dry climate.

There are certain forms of *symptomatic* treatment which should be more widely known. Where spasticity is particularly annoying, small doses of bromides are often of striking benefit. Alcohol in moderate amounts may be useful, and does not seem to be particularly dangerous. The frequency and urgency of urination can often be alleviated by the use of sandalwood oil and atropine. An important point is that the urgency will often pass off if the patient makes up his mind to disregard it or distracts his attention with something else.\* Patients with hemiataxia may learn to avoid staggering by habitually leaning toward the more normal side. The disagreeable sensation of slapping the ground with the toes which is a common component of the spastic gait may often be mitigated by practice in placing the heel on the ground first, and rolling the weight along the outer edge of the foot to the toe. Foot drop may be avoided by orthopedic apparatus. Subarachnoid alcohol injection<sup>†</sup> may be tried for radicular pains.

In the treatment of spasticity, massage and electrical stimulation are to be avoided, as they merely increase the excessive muscle tonus. The foot placement exercises, so useful in tabes, are useless in cases in which the difficulty in walking is the

\* For this and the following suggestions I am indebted to my former associate, Dr. John B. McKeen.

result of intention tremor. Special "telescopic" spectacles are available for patients whose loss of vision from optic atrophy is relatively fixed and constitutes the most disabling symptom. When the bladder is completely paralyzed, an automatic tidal irrigation apparatus should be installed.<sup>21</sup> It also promises some benefit for cases of spastic, irritable bladder. Motorized wheel chairs may be of use to certain patients who are unable to walk.

## CLINIC OF DR. E. GRANVILLE CRABTREE

BETH ISRAEL HOSPITAL

---

### THE TREATMENT OF URINARY TRACT INFECTIONS BY MEANS OTHER THAN THE KETOGENIC DIET

THERE is no perfect universal antiseptic for the treatment of urinary tract infections. Antisepsis alone is far too simple an approach to be adequate for cure in difficult cases. Even if it produces apparent cure recurrence often promptly takes place. For successful combat against stubborn infections other factors besides drug administration must be understood by the attendant physician if he is to be able to furnish that attention to detail which is an essential to success in the treatment of the infection and a safeguard to the patient. A perfect antiseptic for the urinary tract would be a menace to the patient if it permitted prompt removal of the signs of gross disease, which is often infection alone, without that condition having been recognized.

Considered numerically, it is probable that most infections which occur recover spontaneously. Treatment of this group gives abundant optimism for many forms of therapy. The relation of pH to recovery in these cases may be important. That relation is not yet proved. However, I have noted that in my surgical patients in whom urinary tract infection has been introduced in the course of surgery of the bladder or kidney, if prompt clearing of the infections takes place, the urine is almost always quite definitely acid, below pH 5.5, in reaction. Exceptions to this rule are noted.

At this stage in our knowledge of therapy it is sufficient to recognize three types of bacteria, about which we can accomplish considerable in treatment, namely, the colon bacillus

group, *Bacillus proteus* and the gram-positive cocci, staphylococcus and streptococcus. There are some definite differences in the method of attack for cure in the three groups mentioned.

As a preliminary to treatment, identification of the bacteria in the infected urine, and a sufficient number of determinations of the reaction of the urine to indicate the average  $pH$ , is important. Culture of the urine will often be misleading since, in mixed infections, the colon bacillus or *Bacillus proteus* may overgrow and mask the other slow-growing forms of bacteria present, such as staphylococcus. Gram's stain, when applied to the urinary sediment, will help to clear up the question of mixed infections. Culture is necessary, particularly in bacillary infections, to distinguish other forms of gram-negative bacilli, particularly *B. proteus*, from the colon bacillus group. Just how far mutations of bacteria influence treatment has not yet been determined. There is important progress to be made here, particularly in relation to virulence of the infection. At times it seems that in virulent infections acidification of the urine alone may give rise to symptoms in subacute cases. Certainly concentration of urine often gives temperature rises.

Where sugar is present recognition and proper handling is essential to successful treatment. Neither in my own experience nor in the literature, have I found sufficient data to enable me to make a statement as to the significance of high blood sugar readings or the presence of urinary sugar in acidification therapy. If nephritic conditions exist, closer observation of the urine during treatment by acidification therapy would naturally be given to detect signs of irritation early if they should occur. If renal damage is considerable the drug will not be excreted in sufficient concentration to be effective and storage will endanger the patient.

Even where the same bacterium, such as *Bacillus coli*, is the infecting agent, treatment is modified by four conditions in which an essentially normal urinary tract, as distinguished from gross pathologic changes, exists. These are acute febrile infections, subacute or chronic infections, infections in pregnancy and the puerperium, and urogenital infections. Need-

less to say, during acute febrile stages of infection, instrumentation, acidification of the urine, and concentration of urine are contraindicated. In the chronic form of infection one has the most favorable field for medication. In pregnancy there is a physiological dilatation of the pelves and ureters which is to some degree always present in pregnancy and which persists into the puerperium to a degree sufficient to modify treatment. Finally, in the male, pyelonephritis is so commonly complicated by prostatic infection, the symptoms of which are often overshadowed by the renal symptoms, that it is not recognized, receives no treatment and persists as the focus for chronic urinary tract infection with exacerbations. So minor a procedure as catheterization of postoperative retentions in the male with resultant minor degrees of cystitis may initiate such prostatitis which will remain unnoted, but eventually prove to underlie recurrent or persistent urinary infection.

A survey of the extensive studies made, over a considerable period of time, in the value of antiseptics in acute febrile pyelonephritis leads me to two very definite conclusions. The first is that it makes very little difference at this stage of the infection what the infecting organism is. The second is, that any form of active bactericidal therapy is unsound. The bacterium or bacteria concerned are in a virulent state, rapidly growing, producing fever, nausea, often severe vomiting, with attendant acidosis and shortage of fluid intake and excretion. The kidneys are edematous, subnormal in excretory ability and irritated to the point of albumin loss. This is no time for irritants such as hexamethylenamine with acidification, limitation of fluids as required in administration of some antiseptics, the use of heavy metals as in mercurochrome, or arsenicals. The addition of acidity to the acidosis already present especially in the face of diminished excretion, or the burdening of the system with dyes which will be excreted so poorly as to be present in the urine in sub-bacteriostatic or -bactericidal amounts, is equally without supporting logic. These patients have three major requirements. Rest in bed is essential. In home surroundings frequent trips to adjoining bathrooms are

to be discouraged. Even that amount of activity tends to prolong the disease. Vermooten<sup>1</sup> has called attention to the value of the elevated foot and lowered head of the bed with but one pillow as a means of shortening the course of pyelitis. Certainly the bed rest and the cramped sitting postures are to be condemned.

The second requirement is abundant fluid intake and excretion. Diminished excretory ability on the part of the kidneys in their inflamed condition, together with increased toxic products in the blood stream as a result of the febrile state, indicates the requirement for abnormal amounts of fluids to carry away even normal quantities of waste products to say nothing of the increased quantities which exist in the acute illness. If begun early in the disease this fluid can be taken by mouth up to 6000 cc. a day. Four thousand five hundred cc. will be the average requirement. If the patient is toxic when seen, to the point of nausea and vomiting, hypodermoclysis given slowly, preferably by multiple needles, will supply 4000 to 5000 cc. in twenty-four hours. This may either be normal saline or 2.5 per cent glucose. Saline is adequate without the glucose. Intravenous drip may be employed. It is less popular with me because failure to absorb from the tissues is a warning which intravenous fluid administration lacks. Seldom is more than one day of fluid administration by either method required before adequate fluid can be taken by mouth.

The third requirement is alkalization. High degrees of fever and prostration from acute urinary tract infection can be tolerated without acidosis, nausea and vomiting, if sufficient alkali is administered to produce a pH of 7 to 7.5. 45 grains of either sodium or potassium citrate or 60 grains of sodium bicarbonate is usually adequate to produce this result. More should be administered if necessary to produce the result aimed for.

The dangers attendant on instrumentation during acute febrile urinary tract infections are now well recognized. The exception is infection in pregnancy. This exception is made because of the pelvic residual urine which is characteristic of

this disease. Cystoscopic treatment here does far more good than harm. The possibility that an obstruction to drainage might exist, either in the upper or lower urinary channels, must not be lost sight of, but sought for, and promptly relieved where definite findings indicate its presence. Obstruction of ureters by pus plugs is a ghost which has not yet been completely laid. Partial obstructions, as from stones, can be temporized with safety in most instances until some abatement of acute symptoms has occurred.

It should be the purpose of treatment of acute febrile infections to shorten the duration of the acute symptoms as much as possible. Often mismanagement of the early stages of infections of the urinary tract is responsible for troublesome persistence through protracted fevers, starvation, anemias and debility which could have been avoided.

There is no contraindication to a liberal diet including proteins. Development of anemias is often extremely rapid. The alkalized patient need miss but few meals.

A patient emerging from acute urinary tract infections becomes safe for further urological investigation, local treatment or treatment by antiseptics, or for allowing out of bed after not less than four or five days of normal temperature and the loss of renal tenderness. Some patients require a longer delay. Previous to this time intravenous urography is apt to show the kidneys poorly, cystoscopy with retrograde pyelography to cause febrile reactions, and acidification of the urine especially when concentrated for therapeutic reasons to cause a return of fever. The type of antiseptics employed at this time will, in great measure, depend upon the organism found to be responsible for the infection. For the colon bacillus group of bacteria, acidification of the urine with ammonium chloride, sufficient to produce pH 5-5.4, and the administration of hexamethylenamine in 7½-grain doses, three times daily, is usually adequate and up to the introduction of the salts of mandelic acid, was the most efficient form of therapy. I do not see how it is possible to carry out treatment successfully along this line without pH determination. Simple apparatus is avail-

able for the purpose and should be used. Chlorphenol red test paper is of some help if kept in good condition until the time of use. The acidity of the urine is capable of great variation. Without pH determinations valuable time may be lost with the best of intentions toward the patient. Do not forget that old men have already, or acquire during fevers, residual urines. Women in bed are notoriously poor at emptying bladders without leaving residual urine and that both men and women have urethral strictures. Addition of bladder washes with nitrate of silver made up freshly from distilled water at three- to five-day intervals, will clear the bladder walls of adherent pus flakes and débris as well as have antiseptic value particularly in the above cases of small residual urines and the atonic postpartum bladder. A satisfactory silver nitrate solution, almost universally tolerated by the patient, can be made up quickly with 1-grain tablet of silver nitrate dissolved in 16 ounces of warm, distilled water. Do not throw an inflamed bladder into painful spasm with cold solution. Repeated fillings of the bladder are not well tolerated. A second filling will, of necessity, be at a lower capacity from the first if discomfort is to be avoided. Mercurochrome injections of 0.5 to 1 per cent solutions are used. Also argyrol in strength of 10 per cent, or other silver salts are used as an injection after lavage with boric acid solution. Silver is better. If cleansing only is desired, daily lavage with a bland solution such as boric acid solution 2 per cent, potassium permanganate 1:8000, and acriflavine, may be used.

Staphylococcus and streptococcus infections of the urinary tract are usually stubborn infections. Heathcote<sup>2</sup> has shown that the growth of staphylococcus was not definitely reduced at a pH of 5 by three hours' exposure to any concentration of formaldehyde in the urine that could be tolerated by the patient. Treatment by mandelic acid produces some cures. In one of my cases nineteen days of treatment at a pH between 4.7 and 4.9, failed to more than inhibit the growth. Often either acidification with ammonium chloride and hexamethylenamine or mandelic acid has cleared *Bacillus coli* from mixed infec-

tions and left the staphylococci or streptococci in pure culture. If the staphylococcus is still resistant to medication by salts of mandelic acid, alkalization of the urine should be done to a pH of 7-7.5 and acriflavine,  $\frac{1}{2}$  grain in enteric coated tablets, administered three times daily with the urine concentrated by an intake of 1500 to 1800 cc. Another medication, sometimes effective, is methylene blue in 2-grain chocolate-coated tablets administered three times a day. Greenberg<sup>7</sup> has pointed out that the gastro-intestinal symptoms sometimes encountered in methylene blue therapy, are due to zinc salt impurities. Unfortunately the purified dye has not been produced commercially. Where all else has failed neoparsphenamine given in 0.3-Gm. doses at five-day intervals for from 3 to 6 doses, is almost specific for the gram-positive cocci. It is reserved as a last resort because of the dangers attendant upon its administration in a condition by no means of the significance of syphilis. It must be given only after study of the patient and the attendant risk of administration and preferably by one expert in the treatment of syphilis.

Proteus infections will often yield to the salts of mandelic acid. In some of the apparent failures added lavage with silver nitrate has accomplished a cure. In those proteus infections in which acidification does not occur even with heavy doses of ammonium chloride, I know of little that can be done to combat this form of infection. Administration of mandelate or hexamethylamine then becomes wasteful. Fortunately, with all three forms of bacteria, the normal urinary tract is prone to rid itself spontaneously of infections in time. For this reason resorting to elaborate courses of antisepsis, or the more drastic forms of treatment, is hardly justified in the subacute stages of urinary infections.

Shifting from acidity to alkalinity with the avowed purpose of complicating the home conditions of bacteria in the urinary tract has an appealing and delightful simplicity suggestive of the practical joke, the purpose of which seems not often to be effectively grasped by the bacteria concerned. (Note the above remarks on spontaneous cures.) The effect of acidification of

the urine alone is bacteriostatic but not bactericidal in the lower pH ranges of 5.4 and under. No such bacteriostatic action has been recorded for alkalinity in experiments with any form of bacteria. There is no theoretical ground for expecting benefit other than the bacteriostatic effect of acidification when shifts from acidity to alkalinity are made. If acidification is attempted, as is commonly done, by the use of sodium acid phosphate, even that effect is not obtained since strong acidification cannot be produced by this drug.

After the elimination of those acute and subacute infections which either recover spontaneously or reach an early cure by the common forms of therapy, there is left a troublesome remnant of a few cases which are chronic infections. This group has been variously estimated as comprising from 5 to 10 per cent of the whole. They can be grouped into persistent infections or recurrent infections dependent on whether the urine becomes bacteria-free between exacerbations of symptoms. If the urine fails to clear at any time, gross pathology in the urinary tract, particularly conditions of urinary stasis, are probable. If complete clearing of the urinary tract from infections (as demonstrated by absence of bacteria, not pus cells) occurs, the likelihood of gross pathology is less but the probability of systemic causes is greater.

Chronic infections can best be approached for both diagnosis and treatment if the persistence of the infection is attributed to one of three major causes:

1. The condition of the patient,
2. Foci of infection,
3. Gross pathology,

and investigation conducted with the purpose of placing the patient in this classification.

I have already commented on the desirability of intelligent handling of the acute stages of infection that the patient may not emerge from them anemic and debilitated from a protracted illness, and suggested effective measures for the prevention of that condition. Unfortunately, urinary tract infections frequently occur as complications of surgery and debility from

other illnesses. They may then get dug in and reach the state of chronic infections before convalescence from the major illness takes place. Many Americans live in a constant state of exhaustion from overwork and overactivity in an attempt to enjoy *all* the possibilities of our modern life. There is also the faulty diet patient. One such with recurrent autumnal infection was found to have a dislike for summer foods and ate little, lost weight and acquired a yearly autumnal infection. Another patient reaches extremes of exhaustion in her social life. Her infections can almost always be predicted by watching the social columns in the newspapers. A mother, who was a confirmed Christmas shopper, with five children of school age who were all home with their friends at vacation time, had three recurrent infections in the five strenuous years of that activity all of which were in January or February of the new year. I find a higher percentage of recurrent infections in the upper classes with neither foci of infection, nor gross pathology encountered, than in the working classes. The working man has more gross pathology with his pus and bacteria. In addition some chronic infections are cured on adjusting metabolic problems.

Foci of infection seem to me to be the third in importance in these three groups. Teeth, tonsils and sinuses are occasionally incriminated yet it is surprising how often massive sepsis in these areas shows little relation to urinary tract infection either in its presence or after it has been cleared. It is most important in children. It must not be ignored. Bowel conditions play a very conspicuous part both in the incidence and the chronic stages of infection. A chronically overloaded bowel is perhaps most commonly found in these cases, and diverticulitis of the sigmoid is a very serious complication. The occasional case of perforation of such a condition into the bladder must not be overlooked.

In the male a symptomless prostatitis which is participating in a urogenital infection but receiving no treatment is perhaps the most common focus of infection. It may be responsible for a persistent infection with a constantly cloudy urine or for

recurrent infections which take place during exacerbations of prostatitis, which may be even a few years apart.

Gross pathology in the urinary tract either in the form of lower urinary obstruction with bladder residual urine, bladder malformations, diverticula, upper urinary, ureteral and pelvic obstructions all produce stagnant urine from which infection is eradicated with great difficulty by any known means short of correction of the defect. Stones and tumors are the other aids to retention of infections. The physiological changes in the kidneys and ureters due to pregnancy make these cases more nearly associated with this group although the obstructive factor is of necessity limited in duration to nine months. The chief danger is that if the degree of pathology is small the infection might be cured through the more effective measures now available in antisepsis and allow the condition to progress unnoted. Valuable time is often wasted in treatment to the detriment of the patient as in the case of a lady who received 156 pelvic lavages for infected hydronephrosis with stones, after many other antiseptic procedures had failed already. Infection may be the only indication of the presence of serious disease.

The commonly employed urinary antiseptics may be listed as follows: the dye group, the formalin-bearing drugs, the antiseptic acids, and the arsenicals.

**The Dye Drugs.**—Here are found methylene blue, acriflavine, pyridium and serenium, and mercurochrome. There are many others of less importance. All have other properties than the dye property.

Methylene blue, when administered in 2-grain chocolate-coated tablets three times daily in an alkaline urine with a pH above 7, has certain fields of usefulness. Thomas and Wang<sup>4</sup> found it of some value as an inhibitor and less value as a germicide against *Bacillus coli* and *Staphylococcus aureus* when the patient was limited to a fluid intake of 3 glasses of water daily. Hinman<sup>5</sup> found it more effective in staphylococcus and streptococcus infections than in the bacillary group when administered in alkaline urines with concentration. Greenberg used it successfully as a palliative in tuberculosis.

Acridine in doses of  $\frac{1}{2}$ -grain enteric coated tablets three to four times daily in concentrated alkaline urine showed bacteriostatic effects on both bacillary and coccal types of bacteria in half the cases (Walther<sup>6</sup>). Davis<sup>7</sup> had better success with 0.1 Gm. twice daily in concentrated alkaline urines infected with either staphylococci or *Bacillus coli*, producing cures in 13 out of 18 acute cases with 5 failures. In 27 chronic colon bacillus infections there were no cures. I have found it of most value in staphylococcus and streptococcus infections. There are better treatment agents for the gram-negative bacilli.

Pyridium and serenium have had in my hands no appreciable bactericidal or bacteriostatic effect on either the bacillary or the coccal forms of infection. Many other observers agree with this opinion. In a series of experiments in pyelitis in pregnancy the picture presented through the microscope of motile colon bacilli swimming sturdily along through a concentrated urine deeply stained with pyridium, went far to destroy my hopes of much help from these drugs. No other source of experience or information has revived my interest in them.

Mercurochrome, in spite of all that has been written, should be confined in its use to local applications to the pelvis or bladder.

Hexylresorcinol while not a dye drug is discussed here. It is administered in dosages of 0.3 to 0.6 Gm. three times a day and treatment is to be continued two weeks beyond the negative culture. The drug has not lived up to the promise with which it made its initial bow in 1924.

Methylene blue and acridine, even though both may produce gastro-intestinal symptoms, are the most effective drugs in this group. They are applicable to the coccal infections. Other forms of treatment are preferable by far for the bacillary infections. If gastro-intestinal symptoms occur the drug can be resumed after a short rest and tolerance for it seems to be acquired.

**Formalin-bearing Drugs.**—The second group to be considered is the formalin-bearing drugs. Hexamethylenamine is

the form in which this therapy is commonly and most effectively administered. Hexamethylenamine in acid urine has been the best therapeutic measure for treatment of the bacillary group of urinary tract infections previous to the introduction of mandelic acid. In properly acidified urine formalin is freed in antiseptic strength at the kidney level as well as in the bladder, namely, 0.005 to 0.007 per cent formaldehyde. In many instances it is adequate treatment for cure. It fails to cure some strains of *Bacillus coli*. Mitchell and Scott<sup>8</sup> found that certain strains of organisms were resistant to formaldehyde with marked correlation between test tube and clinical studies. If hexamethylenamine killed the organism in the urine, formalin killed it in the test tube. If it failed clinically it failed also in the test tube. The optimum  $pH$  for liberation of formaldehyde from hexamethylenamine in the urine is  $pH$  5–5.4. The common use of sodium acid phosphate with hexamethylenamine does not produce that degree of acidity from alkalinity. It is much preferable to use ammonium chloride to produce the acidity and to observe frequently to note if the proper acidity is maintained during treatment. Ammonium chloride should only be used in enteric coated tablets if gastric symptoms are to be minimized.

So important is acidification therapy both for the use of hexamethylenamine and mandelic acid that the theory and practice of acidification and alkalization should be taken up here.

*Acidification of the Urine.*—The true  $pH$  of normal urine depends in great measure on the phosphates by dissociation of  $NaH_2PO_4$  to  $Na_2HPO_4$  with liberation of an hydrogen ion. With complete dissociation of phosphate the  $pH$  lies commonly between 5 and 5.2. Increase in hydrogen ion concentration is accompanied by increase in ammonia excretion. Urinary volume seems to be inversely proportional to hydrogen ion concentration. Gamble<sup>9</sup> places the lower limits of normal acidity at about  $pH$  4.8 and doubts if acidity can be produced below  $pH$  4. He finds that the upper limit of alkalinity is  $pH$  8, even when large amounts of alkali are administered. Grey<sup>10</sup>

considers  $pH$  below 5, or above 7, pathological. The idea being that the bacterial infections have changed the normal  $pH$ , when figures below and above those readings are obtained. Marlow<sup>11</sup> found in his study of 141 normal young adults that the  $pH$  variation was from 5.1 to 6.8.

Administration of drugs by mouth as acidifiers is an attempt to produce as much free acid radical as is possible to be done. Regulatory factors convey an excess of acid over fixed base into the urine.

The commonly employed acidifiers are:

Sodium acid phosphate . . . . .	20 grains 4 times a day
Ammonium acid phosphate . . . . .	20 grains 4 times a day
Ammonium chloride . . . . .	15 grains 3 to 4 times a day
Ammonium nitrate . . . . .	15 grains 3 times a day
Ammonium benzoate . . . . .	40 grains daily

Sodium acid phosphate has been most widely used for urinary acidification but is the least effective of the group. Stockman and Johnson<sup>12</sup> find that it acts practically not at all in normally slightly acid urine. It produces slight acidity when the reaction of the urine is well on the alkaline side. The ammonium salts of hydrochloric acid, nitric acid and phosphoric acid are the best acidifiers. Their action is due to decomposition of the salt into ammonia and hydrochloric, nitric or phosphoric acid radicals. The ammonia is converted into urea and excreted by the kidneys. The acid is neutralized in the blood and tissues at the expense of the alkali reserve. Serious acidosis does not follow the administration of the usual doses of these drugs if the renal function is good. The same doses with moderate to severe renal impairment may produce marked deviation from the normal acid-base equilibrium with resultant changes in metabolic functions and the production of definite and severe symptoms of acidosis and even death.

It is probably best to select one acidifier and familiarize oneself with its use. Ammonium chloride is on the whole the most satisfactory.

*Alkalinization of the Urine* (Gamble<sup>9</sup>).—Where excesses of fixed base over acid is produced by the administration of al-

kalis there is need for an acid substance abundantly at hand which can be placed in the urine under control. Carbonic acid both suits these requirements and is available in practically unlimited quantities. Routinely it leaves the body base free by way of the lungs, but when needed can, to a regulated extent, be deflected into the urine. The concentration of free carbonic acid in the urine is of a stationary value of approximately the magnitude of that in blood plasma. As a consequence of this fixed value for carbonic acid, excess of base in the blood plasma is excreted as bicarbonate in the urine. Thus as the urinary  $pH$  rises above that of the blood plasma ( $pH$  7.4) the concentration of bicarbonate in the urine becomes greater. This concentration of bicarbonate which, in the presence of a fixed level for carbonic acid, would be necessary to force the  $pH$  of urine above 8 is terminated by the limit of total concentration of substances in urine. It has also been determined experimentally that ingestion of large amounts of alkali will not produce an alkalinity above  $pH$  8.

**Antiseptic Acid Therapy.**—Mandelic acid is a recent addition to our armamentarium for treatment of urinary tract infections. Its place is not yet definitely established. None will deny that for the colon bacillus group of invaders it is the most satisfactory agent yet produced. Many will question its universal application and success with the cocci and some of the less common organisms. The enthusiastic, almost fanatical rush to administer the drug at all times and often carelessly, as regards renal deficiency, acidity and toxicity of the patient in acute conditions has already made some doubt its efficacy. Its use is well established in the steep curve of acceptance with which we commonly greet an important novelty, then condemn and abandon it only later to take it up at somewhere near its true value.

Mandelic acid is a member of the benzoic acid group. It was selected for experimentation as an antiseptic because of all the acids tested it was found to be the most bacteriostatic *in vitro*. It has been known since 1883 that it would be excreted unchanged and not metabolized by passage through animals.

It is impotent except with strong acidity. In vitro at a pH 5.3, all bacterial life is killed at a concentration of 1 per cent. Mandelic acid cannot be administered as acid because of its irritating effect upon the stomach. Salts of mandelic acid must be used as the vehicle by which a proper concentration of the acid is made to reach the urine. As in the case of acidifiers of the urine the ammonium salt of mandelic acid is preferable because the ammonia radical will be excreted as urea leaving the acid free, thereby avoiding an unnecessary base. In an average normal patient, 12 Gm. of ammonium mandelate administered in twenty-four hours will produce a pH 5.3. Helmholtz and Osterberg<sup>13</sup> have demonstrated its diuretic action and cumulative rate of excretion at an established pH 5, with ammonium chloride. It is, therefore, an essentially short treatment course drug. These observers indicated a cumulative rate of excretion from 0.32 to 1.14 per cent in twelve hours during which 12 Gm. of mandelate were administered in 4 doses. They also showed that at a urine pH of 5 and concentration of mandelic acid to 0.25 per cent it was bactericidal for most organisms. The same results could be obtained at pH 5.3 with 0.5 per cent concentration or at 5.7 with 1 per cent concentration. These tests were made using sodium mandelate. They obtained approximately the same results by adding mandelic acid to normal urine of similar pH reading. There is no test for the acid in the urine. These determinations must be made through recovery of the acid from the urine.

Although mandelic acid may be considered as a foreign body in the circulation and in the urine, the need for adequate acidification to ensure its effectiveness introduces the question of acidification which is a chemical process within the body. The two drugs, the acidifier and the salt of mandelic acid, must, therefore, be considered together. Mandelic acid 3 Gm. with sodium bicarbonate 1.6 Gm., combined in solution to form sodium mandelate, is not neutral but has a pH 4.5. In consideration of the use of mandelic acid as an antiseptic one must take into consideration the combined acidifying power of the salt of mandelic acid and the acidifier. Helmholtz and Oster-

berg found that, by measurement of the urea clearance test, a dog suffered no permanent renal damage when 700 cc. of 1 per cent mandelic acid was injected intravenously over a seven-hour period. Presumably the dog had normal kidneys.

Acidification in nephritis, owing to diminished selective secretion by the damaged kidneys, at least justifies reasonable apprehension as to the safety of the procedure. Holling and Platt<sup>14</sup> report 2 cases of renal edema without apparent effect on the nephritis. Lyon and Dunlop<sup>15</sup> observed the CO<sub>2</sub> combining power which they checked before and after the treatment in a number of cases. They found it to be within normal limits except in one case in which 360 Gm. of ammonium chloride was administered in a futile attempt at acidification of the urine. The figure fell from 63 to 46 per cent (CO<sub>2</sub> combining power).

Untoward signs and symptoms may accompany treatment with mandelic acid. The use of acidifiers alone or in conjunction with salts of mandelic acid may produce red blood cells, casts, and albumin in the urine. Cubitt<sup>16</sup> found no ill effects from continued treatment when occasional casts and red cells appeared. Rosenheim<sup>17</sup> found one case with albuminuria showed increased amounts of albumin. In two of my own cases, the appearance of red blood cells was accompanied by bladder tenesmus where no bladder symptoms had been present before. Apparently after prompt cessation of medication all these signs quickly disappear.

The chief symptoms which may occur in the absence of renal insufficiency are buzzing in the ears, temporary deafness, nausea, vomiting, and dyspnea from acidosis. Minor symptoms are acid taste about the teeth particularly about fillings and general uneasiness when either from exercise or climate perspiration is profuse. In renal insufficiency symptoms may be extreme degrees of acidosis and even death.

Administration of the drug has been at the beginning through the use of sodium mandelate. Rosenheim's prescription for its use was 3 Gm. of mandelic acid and 1.6 Gm. sodium bicarbonate with flavoring of lemon and water sufficient to

make 1 fluidounce, put up in 16-ounce amounts. The administration was 1 ounce four times daily. If the acidity of the urine was not adequate, sufficient ammonium chloride was added. Since that time there have appeared other preparations. Ammonium mandelate combined with ammonium chloride in aromatic syrup has been marketed, under the trade name of syrup amdelate. Each fluidounce contains 12 Gm. of mandelic acid. The dose is 2 teaspoonfuls four times daily. Elixir of mandelic acid is also obtainable. It contains mandelic acid, 124 grains, instead of 185 grains, to the fluidounce, as compared with the syrup. Phosphomandelate is also on the market as a combination of ammonium phosphate and mandelic acid. The dosages are provided in separate envelopes with directions. As Cubitt has pointed out and my own experiences confirm, there is great variation in the amount of acidifier necessary to produce the desired pH 5.3 or less, at which mandelic acid acts best, both in different patients and in the same patient at different times. My preference would be for ammonium mandelate without ammonium chloride in syrup form. Sufficient acidifier could be added from day to day as the patient required.

After many and varied approaches, I have found that the most satisfactory method of administering the treatment was through preliminary acidification of the urine, by means of ammonium chloride until pH of 5-5.4 was obtained. This usually requires but from one to three days. Syrup of ammonium mandelate was then administered four times daily under daily observation of the urine. The ammonium chloride intake can be gradually diminished or often dropped altogether in twenty-four to forty-eight hours and the pH held up.\* Most of the cases of bacillary infections become bacteria free in that time. The mandelate is continued at a pH of 4.8-5.2 for a total of six to seven days after which a single dose daily of mandelate with 15 grains of ammonium chloride is administered for six to seven days longer, then the same dose on alternate days for a week more. Fluids are restricted to 1200 cc. for the first week then to 2000 cc. for the second week and fluids as de-

sired allowed during the third week. If recurrence of the infection should take place, treatment in regular dosages as in the first week will usually suffice to eliminate it, but often need not be carried beyond a day or two.  $pH$  readings of 5.5 or lower will often be noted for ten days to three weeks after medication has ceased.

The effectiveness of mandelic acid on both cystitis and pyelitis seems to me not yet to be clearly established. There is general agreement that it is eminently successful in the colon bacillus group of bacteria. Here it is at its best in the absence of any considerable degree of urinary stasis. That it will be successful with some degree of stasis is shown by the successful clearing of 9 out of 13 cases of pyelitis in pregnancy treated after the acute symptoms had subsided. Three of these cases are our own, the remainder collected cases. The proteus bacillus cases have been less constant. Presumably if sufficient acidification can be produced, cure may be effected. Where acidification does not occur it is useless. Both other observers and my own cases show instances where with mixed infections all bacteria are killed, both the bacillary and the coccal forms. In other instances the bacilli are eliminated leaving behind a pure flora of cocci. In one instance with a  $pH$  under 5 for nineteen days coccal infection remained unchanged under ammonium mandelate treatment.

There is no doubt but that complicated cases with gross pathology cannot be looked upon as suitable cases for mandelic acid therapy. It is, furthermore, to be hoped that no other antiseptic will ever be found which, by its use, might conceal to the careless observer pathology of much more significance than the infection which disclosed it.

In the male there are encountered many chronic bacillary urogenital infections. They are persistent over years. Many of these yield to mandelic acid therapy. Usually there are bacilli demonstrated in the renal and bladder urines and in the prostatic secretions. I have treated them in two ways, either by antiseptics first, then by massage, or by a course of massage given previous to antiseptics. In the former group

some persist as pyurias without bacteriuria for a considerable period of time and often recur. The second group is much more satisfactory. In this connection I should mention that several observers have noted that the semen is frequently found stained after oral administration of dye antiseptics. Disappearance of the colon bacillus from the vesicle and prostatic secretions in some of these cases under treatment with mandelic acid might indicate a similar drug distribution.

**Arsenicals.**—For the remnant of intractable coccal infections there is still one form of therapy which offers cure. That is the use of arsenicals. Neoarsphenamine, when administered in 0.3-Gm. doses at five-day intervals for a total of 3 to 6 treatments when required, will eradicate many of the stubborn coccal infections. Its administration is to be taken as seriously as when given for syphilis. There is less justification in producing complications by misuse of the drug when the nature of the infecting agent is of so much less significance than syphilis. Its use in coccal infections should be limited to the chronic type of infection.

Vaccine therapy need no longer be considered seriously in any except the very unusual case.

## CLINIC OF DR. FRANCIS L. WEILLE

FROM THE ALLERGY CLINIC OF THE MASSACHUSETTS GENERAL  
HOSPITAL AND THE MASSACHUSETTS EYE AND EAR IN-  
FIRMARY

---

### STUDIES IN ALLERGY: XXI. IONIZATION IN THE TREATMENT OF HAY FEVER AND VASOMOTOR RHINITIS

IN the treatment of ragweed hay fever by means of ioniza-  
tion, the following report is of interest.

Case I.—A thirty-six-year-old white male patient started having hay fever from the early part or middle of August to frost in 1928, following removal of a cyst from his right antrum. Skin tests by Dr. Francis Rackemann showed sensitization to ragweed and to elm but "inoculations never helped him; they made him worse." Violent sneezing starting with the ragweed season each year made him suffer severely. On August 6, 1935, he had an ionization treatment in a city in New York. He had "perfect relief" through the ragweed season.

On August 11, 1936, the patient came to the writer requesting similar treatment. He had no symptoms at the time. It was agreed that when he became severely ill the treatment would be carried out.

He had only slight symptoms from August 15 to September 6 when terrific sneezing, blocked nose, discomfort in the eyes, etc., started. He was seen for ionization treatment on September 8 while having violent symptoms.

The nasal mucous membrane was cocaineized with difficulty. The nose was packed for thirty minutes with 7 per cent cocaine muriate containing 0.5 per cent ephedrine hydrochloride. Except for slight garrulousness, no signs of a cocaine reaction were observed. Every point of the nasal cavity to be reached by the "ionode" (zinc, cadmium and tin) solution suggested by Warwick for the ionization treatment had to be anesthetized thoroughly both for comfort and in order to prevent expulsion of the packing by sneezing. Moreover the danger of slight displacement of the nasal electrode by sneezing was annoying.

The nose was completely but not tightly packed with cotton strips soaked dripping wet with "ionode" solution. The nasal electrode, described as being made largely of zinc, with small quantities of tin and cadmium was placed within this packing, but not in direct contact with either the medial or lateral

nasal wall. Before testing for the resistance in ohms in the circuit, further solution was added to the packing to soak it completely. It was desirable, but not possible in this case, to have both sides of the nose packed at the same time, as ionization of the first side would assure a low ohmage on the second side.

When ready for connecting the nasal electrode to the machine, the patient was allowed to lie down. The Burdick ionization machine was utilized; while this apparatus is expensive, it is said to be as "fool-proof" as possible. Numerous authors<sup>1, 2, 3, 4</sup> have described this instrument and the technic for using it. A most important point is having a resistance as low as possible, 1500 to 3000 ohms being indicated as desirable. In the present case a reading of about 6000 ohms was obtained. Rather than adjust the packing further, a minute amount of current—about 1 milliamperere—was allowed to flow through the circuit, the arm electrode having been made thoroughly wet and having been applied to the forearm. After about one minute, an ohmage of 4000 was obtained, then 2 milliamperes for two minutes were utilized and 5 milliamperes for one minute brought the resistance down to 3000 ohms. Following this a dosage of 10 milliamperes for ten minutes was given (100 milliamperere minutes). A similar procedure was carried out, but with greater ease, on the other side of the nose.

The lying position was a great comfort to the patient while he was having the treatment.

Upon removing the nasal packing, the mucous membrane had a grayish coating followed in a few minutes by the presence of gelatinous mucus, and later fibrinous exudate. The nasal breathing space was then completely obliterated.

When the patient had his former treatment in New York, fingercot packs had been left in the nose for forty-eight hours, having as their purpose the prevention of adhesions. As the writer has never found by experience that any such adhesions are produced, the patient was told that no such packs would be required. He had found them quite unpleasant, and was agreeably surprised. He was urged to drink fluids freely before his nose blocked completely and thereafter to do as well as possible. Symptomatic drugs, including codeine, were prescribed, especially to relieve headache. He was told to use an ice-cap and to keep his head elevated. He volunteered to keep a detailed report regarding his status following the treatment. It is quoted below without abbreviation.

Tuesday, September 8, 1936:

8.05—Left Dr. Weille's office.

8.10—On way home in the car, teeth in the upper jaw began to ache, particularly the molars.

8.25—Runny nose, both nostrils, watery discharge. Slight burning sensation inside the nostrils. Head clear—no trace of headache. Eyes clear—no tears or irritation in the tear-duct region. Slight impulse to sneeze when I answer questions.

8.30—Supper: appetite not so good. Can swallow water without much trouble—slight bubbly sensation in left nostril when I swallow. Right side completely blocked. No discharge. Left side running. Impulse to sneeze in right nostril easily suppressed.

8.35—Both nostrils blocked.

8.40—Molars no longer ache but front teeth do.

8.55—To bed. Took a glass of water and one of the larger pills.

9.00—Dull pain in front part of the nose. Teeth ache slightly. Temperature: normal.

After lying down experienced throbbing pain in nose. Pain is in rhythm with pulse.

During the next hour nose very uncomfortable. Nervous tendency to waggle lower jaw and grind molars. Breathe hesitatingly. Turn restlessly from one side to the other. Little cat-naps but find it difficult to go to sleep.

During the hour there were five wavelike and painful impulses to sneeze which could be stopped, however.

Some time after 10.30 went to sleep and slept without waking until my usual rising time at 6.30.

Wednesday, September 9, 1936:

6.30—Left side closed. Right side slightly open. (Was sleeping on left side when I woke.) No pain. Watery discharge dripping from left nostril. Eyes clear.

7.00—Breakfast. Little difficulty in swallowing.

8.00—Read morning paper. Right eye bothers a little and nose runs. Want very much to blow nose but refrain due to orders. Clear nose somewhat by gently massaging the front and sometimes clearing my throat. Discharge amber colored. Occasional impulse to sneeze suppressed.

8.15—Felt sleepy and slept again till 9.20.

9.20—Awoke but stayed in bed and dozed.

10.20—Got up and dressed.

Nose runs—watery discharge. Eyes don't bother me while I work. Slight and occasional twinges in right nostril. At such times right eye waters.

11.00—Eyes—especially right eye bloodshot.

Stuffed cotton in nose to prevent constant dripping and read book on Marketing.

11.05—Real twinge which made eyes water—right side of nose and right eye especially affected. Suppressed sneeze.

12.15—Left side a little open. Right side—heavy stuffed-up feeling, after I took out cotton.

12.30—Lunch. Good appetite and no difficulty in swallowing. During the meal the nasal passages cleared so that I could breathe freely.

1.00—Upstairs to nap. Fell asleep at once and slept soundly till 3.50. Breathing through nose—right side.

4.10—No particular sensation in nose with the exception of a slight roughed-up feeling.

4.50—Shaved—usually a delicate operation during hay fever time. No trouble

Breathe through nose but passages not entirely clear.

9.00—Bed and almost immediately to sleep.

Thursday, September 10, 1936:

8.00—Awoke but went to sleep again and slept until 8.00.

8.15—Breakfast.

Had to blow nose twice. Yellow discharge.

Eyes free from irritation. Left side of nose clear. Right side clogged and smarting occasionally.

Little or no trouble during the day.

7.30—Nasal passages obstructed by hardened discharge. Repeated blowing cleared nose but left membranes sensitive—especially the left side.

8.15—Sneezed once in back of throat. Other impulses to sneeze suppressed.

9.30—Bed. Slept until 6.30.

Friday, September 11, 1936.

6.30—Nasal passages filled with loose discharge. Blew nose gently and cleared it without difficulty. Left side wide open but sensitive to every breath. One spot especially felt raw and made my eyes water. Sneezed once.

7.00—Breakfast. Irritation calmed down but watery discharge persisted. Left nasal passage very clear. Right passage somewhat obstructed and sensitive.

Little trouble during the day.

Saturday, September 12, 1936:

6.30—Watery eyes and runny nose.

Clears after breakfast. Little trouble during the day.

Sunday, September 13, 1936:

6.30—Got breakfast and while being near the stove had quite an attack of sneezing, runny nose and watery eyes. Irritation persisted all morning but disappeared after dinner.

Monday, September 14, 1936:

6.30—Runny nose and watery eyes during the early morning. Persisted until 10 o'clock.

Sneezed three times but breathe through nose (both sides) without difficulty.

Following this report all symptoms disappeared.

October 26, 1936: the patient reported no hay fever whatsoever throughout the remainder of the ragweed season.

Because of the favorable effects of ionization treatment clinically upon many cases of hay fever it was decided to utilize this method in certain patients having vasomotor rhinitis. However, in the selection of cases preference was given to "difficult" problems. The following report is of interest.

**Case II.**—An eighteen-year-old white schoolboy had been troubled with nasal obstruction at all seasons as long as he could remember, with profuse watery nasal discharge and 1 to 3 sneezing fits daily. He was inclined to have superadded "colds" (apparently hay fever) in summer, with which he wheezed, but not severely. Straightening his septum, and removal of the tonsils and adenoids had not helped him. He was found to be sensitive to ragweed and timothy and to orris, house dust and kapok.

Examination of the nose showed a pale, boggy, granular nasal mucous membrane, with watery secretion in the middle meatus. The septum was still

somewhat deviated to the left, and its swollen mucous membrane made it appear thickened. The sinus x-rays were normal.

All manner of treatment, allergic or otherwise, failed to produce improvement and in March, 1935, Warwick ionization treatment of the nose was done. Complaints of watery discharge and sneezing then very largely disappeared, but the nasal obstruction remained very annoying despite definite thinning of the mucous membrane. The fact that there still remained a moderate high deviation of the septum to the left which had prevented the packing from being as effective on the left side as on the right, may have explained in part the greater mucous membrane thinning on the right side of the nose.

On June 28, 1935, the patient reported hay fever of a few days only with wheezing for about a week. Five days later he reported his nose as being excellent—no sneezing and one side of the nose constantly open.

The next year, in March, 1936, he was again advised to have ionization treatment. At this time the nasal mucous membrane was pale, but thin on the right side while very swollen on the left side. Warwick ionode packs were left in the nose for an hour, but no ionization was done. On July 28, 1936, he reported that he had been better for two weeks following this treatment, but after that his nose had been "terrible and as bad as it had ever been," chiefly because of nasal obstruction. Nasal discharge and sneezing no longer bothered him, nor did wheezing.

In an effort to increase the nasal breathing space, the anterior tips of the middle turbinates were removed. The pathological report was "considerable fibrous tissue for man of this age; epithelial surface denuded; in some portions of section there are questionable epithelial casts present in the gland ducts."

This case suggests that actual ionization is more effective than packing with the same solution, and that the treatment is more effective in relieving sneezing and nasal discharge than nasal obstruction in vasomotor rhinitis.

The effectiveness of both subepithelial diathermy cauterization and of ionization therapy is illustrated in the following report:

Case III.—A thirty-seven-year-old female patient had suffered from nasal obstruction, a dozen or more sneezing fits daily, watery nasal discharge, lacrimation and itchiness of the palate for many years. Her symptoms always continued throughout the year but were worse in the spring and fall. She had noticed that dust, tobacco, and face powder made her "terrible." A trip, away from the house where she had lived for ten years, to the mountains had been accompanied by improvement. A septum operation two years before had helped her for a few months. She had never had asthma.

Skin tests by the scratch method were negative; by the intradermal method an irritative skin was found. The nasal mucous membrane was very pale and extremely boggy. It responded poorly to strongly shrinking drugs. The sinuses were normal both clinically and on x-ray examination.

No real improvement resulted from various forms of medical treatment, so that subepithelial diathermy cauterization of the nasal mucous membrane was advised and carried out. Under local anesthesia diathermy coagulation of some of the stroma of each inferior turbinate was accomplished through a stab wound made with a long needle-like electrode. The resulting reaction in the nose lasted about two weeks. Following this treatment the patient was completely "cured" for five years. In May, 1936, her symptoms all returned. Her nasal mucous membrane appeared very pale and boggy. She became worse during the next few weeks, and in June, 1936, the nose was packed with Warwick ionode materials. The right side only was ionized. A gray deposit was observed on the mucous membrane of both sides when the packing was removed. Three days later, thick fibrinous membrane was observed in both sides of the nose. Microscopic examination of this membrane was reported: "Fibrinous exudate; no tissue recognized. Many eosinophiles are present."

In another week the nasal mucous membrane was found to be pink and thin and all symptoms had disappeared.

The patient was observed throughout the summer and fall; at the end of October she still remained symptom free.

One would suspect from this case that if both sides of the nose are packed, ionization occurs bilaterally when one side is ionized.

The value of subepithelial diathermy cauterization of the nasal mucous membrane is strikingly illustrated in this case. A prolonged follow-up will be necessary to determine the comparative effectiveness of the ionization therapy.

**Discussion.**—The most important point to consider in advising ionization therapy is the effect of the treatment upon the nasal mucous membrane. Two findings have been observed microscopically in biopsies from 4 cases after ionization: a fair amount of fibrosis of the stroma and metaplasia of the ciliated epithelium. The former presumably tends toward stabilization of an unstable mucous membrane. The latter places some doubt theoretically upon the desirability of using the method. However, from the practical point of view no adverse effects upon nasal physiology have been observed. Mosher<sup>5</sup> believes that such epithelial metaplasia may be disregarded as relatively unimportant in these cases.

Fibrosis of the stroma is seen after any type of nasal cauterization—from simple use of silver nitrate to subepithelial diathermy coagulation. Mosher<sup>5</sup> feels that ionization is merely

a refinement of such methods. There is the added advantage, however, that adhesions between surfaces never result from it, and that numberless sensitized surface cells are sloughed off.

So far as the effectiveness of the method clinically is concerned, it probably compares favorably with allergic desensitization treatment. It is likely to fail in cases having pathology other than mucous membrane instability which prevents adequate packing of the nose or which outweighs in importance the actual state of the mucous membrane.

**Conclusions.**—1. From patient's point of view the treatment may be exceedingly successful, as in Cases I and III, or rather disappointing as in Case II.

2. Actual ionization is clinically more successful than simple prolonged packing of the nose with the same solution, unless one side is packed and the other ionized at the same time.

3. The great theoretical drawback is that the treatment produces metaplasia of the epithelium. The fibrosis of the stroma which is induced is probably valuable in tending to stabilize the nasal mucous membrane.

4. The treatment itself is not particularly disagreeable to the patient.

5. The after-effects cause pronounced discomfort lasting for a day or two and gradually subsiding.

### COMMONLY MISSED DIAGNOSES IN DERMATOLOGY

THE simple, everyday diseases of the skin are the ones which are frequently missed: psoriasis, scabies, seborrheic dermatitis, dermatitis venenata, epithelioma, etc. One may find, particularly in the state medical journals, many previous attempts on the part of practicing dermatologists to elucidate the commonly missed diagnoses of cutaneous medicine. In these papers, the list of diagnostic problems includes predominantly the usual skin disturbances with which most physicians are quite familiar, at least by name.

It seems that, in the practice of medicine, diseases of the skin appear much less often in classical form than they do in more or less atypical varieties, and the moment a skin disease becomes atypical, confusion arises. This confusion often disappears when the patient undresses completely and is carefully inspected from scalp to feet. Other areas of involvement are then found, often unknown to the patient, and some of these may possess diagnostic features which are lacking in the area representing the presenting complaint. The patient's denial of involvement of areas not open to ready inspection is often misleading, and his opinion regarding the status of his scalp or feet is always worthless. Collateral evidence of the greatest value is often found in these upper and lower poles of the body.

The specialist obtains a great advantage by the simple expedient of examining doubtful dermatoses with the binocular loupe. This advantage is available to anyone sufficiently zeal-

ous to make the purchase, and enlarges the readily available morphological data immensely.

Important evidence may be obtained in many cases by gentle curettage of lesions associated with dried exudates and secretions. An otherwise forbidding lesion may be reduced to great simplicity by removing well-guarded accumulations of detritus. Likewise, the true nature of more serious lesions may be revealed.

The time-honored dermatological custom of examining the patient before obtaining the history has justifications. An hour or more could easily be consumed in recording a detailed story from an introspective scabetic. Such a history would become immediately in large part worthless the moment the scabetic burrow was identified.

On the other hand, examination prior to history taking encourages snapshotism, and is apt to lead to undue subordination of the history. In the consideration of difficult diagnostic problems, a careful history is immensely valuable; its assistance is too often lost in a hastily executed survey of the case, and in overzealous confidence in the value of pure skin morphology as a sole diagnostic criterion. A vast amount of the common cutaneous ailments are either borderline or nondescript in character, and an opinion based purely on inspection has more the quality of guesswork than would be the case if properly reenforced by evidence pertaining to possible gross dietary aberrations, alcoholism, excessive nervous wear and tear, foci of infection, internal diseases under treatment by other physicians, sources of contagion, occupation, hobbies, etc.

A carefully analyzed story of the present illness is usually the most helpful part of the history, but, if this does not provide diagnostic clues, a surprising amount of valuable information can often be dug out of the other parts of a routine general history of the case. Such a history is vastly more important than a routine physical examination.

It is clear that bacterial and fungus infections, local irritants, internal toxins, and the various allergies may each produce more than one type of reaction in the skin. It is also

clear that a given morphological picture, such as the eczematoid, may be produced by several, if not many, various agents. Dermatology is thus full of pitfalls.

One of the most helpful aids to accurate clinical diagnosis in dermatology consists in making a list, either actually or mentally, of the possibilities which are suggested. One then takes up each alternative diagnosis in the differential, and attempts to exclude it or to prove its plausibility on the basis of details in morphology and distribution, as well as on the basis of other evidences from the general work-up of the case. An attempt is made to avoid snapshotism, and one avoids a precipitate answer to the patient's query as to what he has; a query frequently made the instant the doctor lays eyes on the eruption, and before he has had a chance to weigh all the evidence. Each lesion is carefully and separately examined, and the distribution is noted. As a case is inspected, going systematically from head to foot, various possibilities are suggested as each region is viewed. These suggestions are recorded, perhaps in writing, along with a list of all available data. It may then take hours or several days to correlate the data in hard problems. With practice, a clear answer emerges more and more easily from a mass of confused data.

This process of making a mental list of the possible diagnoses, and then of analyzing the list carefully is far superior to the usual approach of merely looking at an eruption and waiting for inspiration.

A list of the commonly missed diagnoses of the skin has been prepared. This list represents a collection based on personal experience, as well as on opinions collected from other papers dealing with this subject.

These diagnoses may be listed as follows:

Dermatitis venenata, including not only dermatoses due to vegetable poisons but those due to other chemical contacts. The general group of contact dermatoses and industrial dermatoses are thus included.

Epithelioma.

Psooriasis.

Seborrheic dermatitis.

Dermatitis factitia (self-inflicted lesions of the skin).

Pityriasis rosea (often confused with *tinea corporis* and secondary syphilis).

Erythema multiforme (often confused with urticaria and pemphigus).

Scabies.

Impetigo circinata (often confused with *tinea circinata*).

Bullous impetigo (often confused in the newborn with syphilis and pemphigus).

Herpes zoster.

Acne rosacea (often confused with *acne vulgaris*).

Dermatitis medicamentosa.

Lichen planus.

All forms of cutaneous syphilis.

Miscellaneous conditions such as coccidioidal granuloma, granuloma annulare, and lichen simplex chronicus.

Space does not permit a complete discussion of the differential diagnosis of all of these diseases of the skin. The list, itself, should prove serviceable as a guide to the practicing physician who would like to improve his diagnostic acumen. In the presentation of cases which follows, pertinent comments will be made in regard to important diagnostic criteria.

The selection of cases was made less in the hope of making it a comprehensively illustrative group than with the desire of presenting instructive as well as interesting cases. The main contribution of this paper lies in the case reports which purport to illustrate to the practicing physician a few points in the technic of diagnosing commonly missed skin diseases.

Case I.—G. M., a married woman of fifty-nine years, had been under observation for seven years with a dermatosis affecting the inner aspect of each thigh. Complete routine medical studies had been carried out several times. The skin and circulation of the lower extremities had received investigation in the hands of specialists. Almost every conceivable laboratory procedure had been carried out and no satisfactory interpretation or treatment for the dermatosis had been found. The patient was considering a pilgrimage to distant medical centers for further guidance, when the diagnosis was established by the simple procedure of examining the entire skin.

Inspection of the thighs themselves revealed on the lower inner aspect of each a large solid plaque of erythema, edema, and scaling with considerable lichenification and excoriation due to scratch. The true nature of the disease was completely disguised by the effects of scratch. It required considerable persuasion to induce the patient to remove her shoes and stockings to permit examination of her ankles and feet, and it was weeks before she would consent to a detailed examination of the scalp. A grade A dermatologist had been entirely satisfied with local examination of the thighs and had missed the diagnosis.

Inspection of the ankles revealed typical patches of psoriasis. There were well-circumscribed, raised plaques of erythema with characteristic layered, silvery psoriatic scales and bleeding points. There were similar patches in the scalp. It was then recognized that the plaques on her inner thighs were also psoriatic, bearing a very close resemblance to other areas as regards tint of erythema, elevation of the plaques, and sharp margination. The secondary changes due to scratch had resulted in such a degree of lichenification and excoriation as to disguise the nature of the disorder. This case was made elusive to a further extent due to the total absence of affection of the elbows and knees.

The diagnosis of psoriasis explained the resistance of the disease to treatment, particularly since treatment for psoriasis had never been carried out.

Case II.—W. B., an energetic young woman of superb general health, had been under treatment for two years by a grade A dermatologist, who had reported to the referring physician that the patient had "lichenification of the right elbow."

Examination of the right elbow revealed a typical psoriatic plaque with layered, silvery scales and bleeding points. At the time of the first examination, there were no such plaques to be seen anywhere except on the right elbow. During the subsequent year and a half of observation, typical psoriatic lesions appeared on the scalp, legs, thighs, and right knee.

The diagnosis was evidently overlooked in this case due to the fact that the first dermatologist who saw the patient was not curious enough to scrape the elbow. Had he done so, he would have recognized immediately the layered, silvery scales and the bleeding points of psoriasis. Observation of this patient over a period of eighteen months proved beyond all possibility of doubt that she had psoriasis.

Case III.—F. S., a married woman of twenty-seven years, consulted a grade A dermatologist for some blotchy lesions recurring on the face during the spring of each year. The dermatologist was satisfied with a simple inspection of the facial lesions, which he regarded as a neurogenous disturbance.

The lesions persisted as usual for two or three months and then vanished with the advent of early summer.

In the following year, the same lesions reappeared during the spring, and a second dermatological opinion was sought. Inspection revealed a papulopustular eruption, suggestive but not distinctive of psoriasis, until the lesions were carefully curetted. The typical layered, silvery scales and the bleeding

points of psoriasis were then demonstrated. Identical lesions were found in the scalp and on the back, but the elbows and knees were clear.

*Discussion.*—Many other missed cases of psoriasis could be added to the above.

It is inconceivable that a typical case of psoriasis would be missed by any well-trained physician. A high percentage of cases are, however, sufficiently atypical to become extremely elusive. It is a frequent occurrence for the elbows and knees to be spared, and this is very misleading. The patches themselves may not suggest psoriasis at all until scraped. The habit of scraping papulosquamous lesions will frequently reveal diagnostic layered, silvery scales and bleeding points in cases in which psoriasis is not at all suspected at first glance. Likewise, patches of erythema, not apparently scaly at all, may prove on curettage to possess even extreme layered psoriatic scaling. Also, the habit of careful examination of the scalp will often reveal classical patches of psoriasis, unknown to the patient, and these may arouse the suspicion necessary to recognize atypical psoriatic patches elsewhere.

There is no area of the body which may not be affected with psoriasis. The patterns of distribution are innumerable. Frequently, only one solitary patch is to be found. The mistake of examining only the area of skin presented voluntarily by the patient, as the chief complaint, is a common source of error.

*Case IV.*—M. H., a college student of twenty years, had eczema in childhood from the age of five to ten years, and had been having urticaria off and on most of her life. During recent years mild urticarial attacks had come about every six weeks. She had long known that she could write her name on her skin (dermatographism).

Seven months prior to dermatological consultation, while visiting in the Midwest, she began to notice severe generalized pruritus, marked exacerbation of her old urticaria, and occasional blisters on her fingers. There was definitely no suggestion of nocturnal exacerbation of itching.

Upon returning to the East, medical advice was sought, and her case was exhaustively studied. Complete general medical investigations were carried out. A thorough allergic study was done. Scratch tests showed definite reactions to timothy, orchard grass, and ragweed. Treatment by means of ephedrine, hydrochloric acid, and other measures was totally ineffective.

After seven months of study and treatment, the patient was referred for dermatological opinion. Examination disclosed on the upper back many excoriations and a number of faint macular lesions. On each side of the neck and upper chest, there were diffuse erythematous plaques with a moderate degree of lichenification and scaling. The scalp and feet were negative.

Between the thumb and index finger of the right hand there was an insignificant, dry crust evidently due to scratch, but it was interdigital and served to stir a very faint suspicion of scabies. On the right thumb there were two discrete, thin-walled vesicles. These vesicles definitely did not suggest scabies. There were no burrows, and there was nothing about the general distribution to suggest scabies. Except for the areas mentioned, the skin was completely devoid of changes.

Knowing that scabies is difficult to diagnose in persons of good hygienic habits, the vesicles were thoroughly fished, but no Acari were found.

Reexamination of the patient after a week of palliative treatment revealed on the right little finger a very small burrow. This burrow was fished and a typical *Acarus scabiei* was found.

The patient responded immediately and permanently to the twenty-four-hour treatment for scabies. At the last examination, seven months following treatment with two applications of Danish ointment, there was no return of itching and no evidence of scabies.

*Discussion.*—Scabies has been justly designated as at once the easiest and the most difficult diagnosis in dermatology.

In an exceedingly entertaining article concerning "Scabies Among the Well-to-do," Stokes<sup>1</sup> reports 53 cases of scabies from his private practice. The reader is referred to this article, the perusal of which is sure to improve his scabetic diagnostic acumen. Of these 53 cases, 37 had seen one or more physicians without relief; 8 had been seen by grade A dermatologists, and in 5 of these, diagnostic errors had been made. A total of 10 correct diagnoses had been made among 49 physicians who saw 37 of the patients.

Stokes lists as causes for the failure to diagnose scabies the following: (1) "a low index of suspicion"; (2) unfamiliarity with the typical scabetic burrow syndrome; (3) failure to see or recognize the burrow without the use of the lens; (4) failure to distinguish between scabies and the complications or sequelae, etc. The commonest erroneous diagnoses were: (1)

<sup>1</sup>Stokes, John H.: Scabies among the well-to-do: some principles illustrated by the case. Jour. Amer. Med. Assoc., Vol. 106, No. 9 (Feb. 29), 1936.

nerves; (2) hives (the scabetic urticarial reaction); (3) dermatitis (scratch plus pyogenic infection).

The diagnosis of scabies must rest chiefly on four observations (Stokes):

1. The burrow, especially on the hands and on the penis.
2. Nocturnal itching.
3. Distribution.
4. Identified contact.

**Case V.**—S. M., an engineer of forty-eight years, had been under treatment for two years for chronic ethmoid sinusitis. Ten months prior to dermatological consultation, he began to suffer from attacks of a dermatitis affecting the skin of the alae nasi, upper lip and adjacent portion of the left lower cheek, as well as the mucous membranes of the anterior portions of the nasal passages and the nasal septum. The eruption consisted of erythema, edema, scaling, crusting, and papulovesicular lesions.

The referring physician regarded the eruption as a dermatitis of bacterial origin, spreading from the sinuses. He thought that he cleared it up slowly by argyrol applications and lamp therapy. However, he could not prevent recurrences and sought dermatological assistance, not for diagnostic purposes but in the hope that x-ray therapy or some other special treatment would have more lasting effect.

The mystery of this case was solved by a carefully elicited story of the sequence of events involved in the present illness. A complete history in all other respects was entirely irrelevant.

**Present Illness.**—Twice per month for ten months the patient developed a frontal headache and a deep sense of stuffiness in the head. On each of these occasions, he employed a nasal spray. The headache and sense of stuffiness would then clear and a watery nasal discharge would set in. Exactly two days following each of these episodes, the skin eruption would appear. The use of cold cream, lenigallol, and other local preparations was ineffective in preventing the eruption.

The above story shows a close relationship between the induction of nasal discharge and the appearance of the eruption. One would naturally conclude that the discharge came from the sinuses and carried bacterial contaminants which invaded the nares and upper lip.

On the other hand, the nasal discharge was distinctly watery rather than purulent, and was more suggestive of hay fever than of sinus drainage. Subsequent studies proved that this discharge might well have been a sensitization reaction similar to that of vasomotor rhinitis or hay fever.

In the absence of knowledge pertaining to the exact nature of the nasal spray used, it was assumed that it might have been ephedrine. Accordingly, a standard preparation containing ephedrine in oil was obtained at the pharmacy, and was used in a patch test, carried out in a standard manner, using cellophane and a broad strip of adhesive tape.

When interpreted in forty-eight hours, this patch test with ephedrine was entirely negative.

Subsequently, the patient brought a bottle of the nasal spray which he had actually been using. A patch test performed with this material was violently positive. When the patient reported to have the test interpreted, he complained of intense itching at the site of the test. Removal of the adhesive revealed intense erythema and edema with innumerable tiny vesicles closely packed together.

Later it was determined that the patient had been using metaphedrine inhalant as a spray. Since his patch test was entirely negative to ephedrine, it was presumed that he was sensitive to the metaphen in his spray.

Treatment consisted simply in replacing the metaphedrine spray with an ordinary ephedrine spray. During the ensuing five months, he remained entirely free of his skin eruption. At the end of this time he developed a very mild, evanescent skin eruption of the upper lip. Except for this, the patient remained completely clear and was still having no trouble whatsoever at the time of his last written report ten months after avoidance of metaphedrine spray was advised. This ten months' record was in striking contrast to the preceding ten months, during which he had violent attacks of dermatitis twice per month.

It seems likely that his periodic watery nasal discharge was attributable to the effect of metaphen sensitization on the nasal mucous membranes.

**Case VI.**—H. W., an elderly retired business man, had consulted specialists in London and physicians on a transatlantic liner en route to the U. S. A. without obtaining any information regarding an extremely pruritic generalized eczematoid eruption.

Upon arrival in this country, his case was exhaustively studied by an internist. To both internist and dermatological consultant, the case was at first regarded as a considerably puzzling problem.

A second examination of the skin itself revealed certain peculiarities of distribution which solved the problem completely and paved the way for an extremely swift therapeutic result.

The morphological findings consisted of erythema, edema, scaling, fine papules and papulovesicular lesions, and numerous superficial ruptured vesicles.

The face, the hands, and the feet were entirely clear. The legs were involved only to a level just above the edge of the shoes, where the eruption ended abruptly at the lower border of some long woolen underwear which extended beneath the socks to just above the shoe level. The entire legs were involved from the knees to the ankles, but there was particularly intense affection beneath the garters which apparently increased the pressure and friction from the woolen underwear.

The thighs were less affected on the extensor surface than on the flexor surface, probably as a result of increased pressure and friction from the sitting position.

A sharply outlined band of dermatitis extended completely around the waistline. This area was coincident with contact with a woolen band which he had worn around the waist for some years.

The arms were clear but the forearms were markedly affected. A silk undergarment served to protect the arms, but below the elbows, there was contact with a woolen shirt.

The obvious deduction from the above facts was that this patient was suffering from a wool dermatitis. Upon reviewing the history, it was found that the patient had an attack of bronchitis in early September and because of this, began to wear the woolen garments mentioned. Shortly after this, his skin eruption began.

In treatment, all woolen garments were discarded and intimate contact between clothes and skin was limited to silk, linen, and cotton. Local treatment consisted of simple, soothing applications. All preparations containing lanolin were avoided because of the lanolin sensitization which, occasionally, accompanies wool sensitization. Because the patient was anxious to recover as rapidly as possible, calcium and hydrochloric acid were administered by mouth in the hope of expediting involution.

On the above plan of treatment, there was striking fading of the eruption in one week and almost complete clearing in two weeks.

During treatment, the flexor surfaces of the thighs relapsed and the dorsal surfaces of the hands became involved. Investigation revealed that as he was able to get around more, he began wearing a heavy woolen suit. He had not yet purchased long linen underwear to protect his legs and the chief area of contact with the woolen suit was brought about, in the sitting position, between trouser legs and flexor surfaces of thighs. The wearing of long linen underwear promptly cured this relapse.

Furthermore, it was noted that when sitting around in his woolen suit, he was in the habit of folding his hands and dropping them in his lap in a manner causing contact between the backs of his hands and his woolen trousers. Avoidance of this habit permitted rapid clearing of the hands.

One of the very interesting features of this case was the fact that the patient had been a wool merchant all of his life and, for many years, had worn, in the winter, garments identical with those to which he was obviously sensitive. In analyzing these cases, one usually searches for recent unaccustomed contacts and one tends to discredit the possible rôle of contacts which have been present without mishap for years.

The reason why this patient should have become suddenly wool sensitive after so many years of evident freedom from it, is food for thought. Careful analysis of all data in the case revealed nothing which was recognized as a clue in this regard.

Case VII.—L. S., a middle-aged business man, consulted his family physician because of an acute eruption of the hands and face. The dermatosis was regarded as very puzzling, and dermatological assistance was obtained.

Examination revealed an acute dermatitis made up of large amounts of

erythema and edema. Close inspection disclosed areas in which innumerable fine vesicles were closely crowded together as is often seen in poison ivy. Also, there were several lesions in which vesicles were seen to run distinctly in the lines of scratch.

The diagnosis of dermatitis venenata was made, and questioning soon revealed that for two weeks the patient had been caring for a primrose plant, pulling off leaves and breaking stems with his hands. The vegetable toxin was thus deposited upon his hands and was inevitably carried to the face.

*Discussion.*—There is probably no dermatological diagnosis more commonly missed than contact dermatitis. It is impossible to transmit by the written or spoken word that partially intuitive knowledge which enables the eye to suspect these cases. Having seen enough proved cases of dermatitis venenata in typical form, one acquires a distinctive mental picture of erythema, edema, and vesiculation. It helps to remember that on the face, the eyelids are apt to undergo rapid and extreme swelling. It also helps to know that the vesicles are likely to be small and exceedingly numerous, usually being closely packed together. It also pays to remember that bullae of varying sizes may be present among these small vesicles and that the vesicles may run in the lines of scratch.

A given contact dermatitis may, on the other hand, stir not the slightest suspicion of its true nature even to the eyes of the most experienced. In these cases, careful analysis and deductive reasoning will save the day.

**Case VIII.**—B. P., a widow of forty-seven, was considerably perturbed because of the sudden appearance of a circinate lesion on the chin. She sought the advice of her family physician who made a preliminary diagnosis of *tinea circinata*, but was not entirely sure of his opinion, and sought dermatological assistance.

Examination disclosed a circinate lesion made up of a very superficial "stuck-on" type of crust and the remains of a ruptured circinate bulla. There were no vesicles, no scaling, and no evidence that the lesion had developed as a consequence of the spread of a small lesion peripherally with central clearing; such as would take place in the development of a patch of *tinea circinata*.

The findings were typical of *impetigo circinata*.

**Case IX.**—M. M., a married woman of thirty-six years, was referred from a small outlying community. An appointment was made in the most urgent terms and the case was represented as an emergency. The patient and husband appeared in an utterly frenzied state of mind. For a week the most rigid

hygienic precautions had been observed for the prevention of spread, of what was definitely regarded as secondary syphilis, to the several children or to the husband.

Examination revealed an extensive papulosquamous eruption, which in general was quite consistent with secondary lues. Furthermore, there was total absence of itching, and there were constitutional symptoms consisting of pain in the back and knees. Because of this combination of symptoms, there was every justification for suspecting syphilis.

Inspection of the skin revealed on the left breast a large, oval, fawn-colored, markedly scaly lesion, strongly suggestive of the "mother spot" of pityriasis rosea. This lesion was much larger than any of the rest, and the patient volunteered the information that this spot had appeared about ten days or two weeks prior to the outbreak of the general eruption.

Elsewhere over the trunk, arms, thighs, and neck there were numerous oval, fawn-colored, scaly lesions, some showing a tendency toward central clearing and many running definitely in the lines of cleavage of the skin. There were no lesions below the knees, very few below the elbows, and none on the face.

Therefore, in all respects of morphology and distribution, the eruption was typical of pityriasis rosea. The total absence of itching was entirely consistent with pityriasis rosea. The confusing constitutional symptoms consisting of pain in the back and knee joints were found, upon more detailed analysis, to antedate by several months the onset of the skin eruption, and were, therefore, probably not related to it.

The laboratory studies consisted of dark-field examination and blood serological tests for lues.

One of the more prominent lesions was curetted until a slightly blood-tinged exudation of serum was elicited. The usual dark-field preparation was then made, and a diligent search for *Spirochaeta pallida* was carried out. The search was entirely negative.

To provide an immediate further basis for reassurance of patient and husband, a specimen of blood was tested by the Rapid Hinton method. This test was negative. The usual Wassermann, Hinton, and Kahn tests were done at the first visit, and these were repeated one week later. All six of these tests were negative.

Thus it was proved that the patient had pityriasis rosea rather than secondary lues.

One week following treatment with an erythema dose of ultraviolet light and local applications of 30 per cent aqueous solution of sodium thiosulphate, there was striking improvement of the eruption.

*Discussion.*—The mistake made in the above case was obviously a more healthy one than would have been the reverse. It would have been vastly worse to diagnose a case of secondary lues as pityriasis rosea and permit spread to others in the family. Furthermore, the case had puzzling features, and, in

accordance with the strict rules of this differentiation, the final opinion rested upon laboratory data.

In all supposed cases of pityriasis rosea, serological studies to exclude lues should be made routinely. An expert dermatologist is seldom wrong in his clinical appraisal of this differentiation. On the other hand, no physician can regard his clinical diagnostic acumen as great enough to ignore the routine of doing a Wassermann to prove the correctness of his diagnosis.

Case X.—C. J., a married man of forty-two years, consulted a general practitioner, promptly following the appearance of a penile lesion. The patient's emphatic denial of extramarital exposure when joined with a negative blood Hinton test apparently were very misleading to the general practitioner, who treated him for two weeks with local applications, thus depriving the patient of his golden opportunity for treatment in the seronegative primary state of syphilis.

When the patient failed to respond to dermatol and other local applications, he was referred for dermatological advice.

Inspection revealed on the glans penis two shallow ulcerative lesions with definite cartilaginous induration and extreme edema of the foreskin. There was marked bilateral inguinal adenopathy.

Because of the previous use of antiseptic local applications, it was impossible to demonstrate *Spirochaeta pallida* until after prolonged search of 8 separate preparations was made. Twenty-four hours later, after several normal saline soaks of the penis had been carried out, repeat dark-field examination revealed numerous typical *Spirochaetae pallidae*. A Rapid Hinton test was positive and routine Wassermann, Hinton, and Kahn tests were positive. Repeat Hinton and Kahn tests were positive, but the Wassermann was negative.

The diagnosis of primary syphilis was established on the basis of dark-field examination alone though it was supported by a Rapid Hinton test. Other serological evidence coming later was merely confirmatory, for antiluetic treatment had already been started. Had all serological tests been negative, the diagnosis would have been equally clearcut. The clinical evidence alone was almost incontrovertible. A positive dark-field was all that was needed for an absolute diagnosis and for prompt institution of treatment.

The diagnosis or exclusion of early syphilis must rest entirely on laboratory procedures. In the early primary stage, only the dark-field examination done strenuously by an expert can be relied upon because the serology is frequently negative.

As in the above case, denial of exposure, sterling personal characteristics, and negative serological tests for syphilis do not exclude syphilis.

Case XI.—W. B., a young unmarried man of twenty-one years, was referred for diagnosis.

Examination revealed a small, dry, pale, smooth, inconspicuous papule on the glans penis. There was no satellite adenopathy and nothing about the skin lesion itself to suggest its specific nature. Wassermann, Hinton and Kahn tests were all negative.

Dark-field examination revealed nothing in the first four preparations, but reexamination on the following day revealed numerous typical *Spirochaetae pallidae* in the first preparation studied.

Case XII.—Mrs. G. S., a middle-aged woman, had been under expert medical and dermatological supervision at frequent intervals for sixteen years. She was referred for dermatological advice regarding a number of trivial cutaneous complaints including a great many seborrheic keratoses and verrucae about the face.

A systematic examination of the face, ears, and scalp was carried out. Behind the right ear was discovered a medium-sized typical epithelioma, consisting of a hard, infiltrated plaque with a raised translucent border and a nodule in the upper margin. The center of the lesion was excoriated, but not ulcerated, and was occupied by a small blood clot.

A clinical diagnosis of epithelioma was made. The lesion was removed by surgical excision and showed on microscopic examination the typical histological features of basal-cell epithelioma.

Case XIII.—Miss R., a middle-aged spinster, had been under close medical observation for about one year. Several consultants were seen for various ailments but no one had paid much attention to a lesion on the right side of the nose. Finally she was referred rather casually for dermatological advice.

Examination disclosed a typical epithelioma located on the right side of the nose. The lesion measured 10 mm.  $\times$  7 mm. and was so distinctive that there could be not the slightest doubt regarding diagnosis. The border was raised and translucent, and the center was depressed. It was firmly indurated and moderate telangiectasia was present. There were several distinct nodules in the border.

Case XIV.—B., a retired business man of sixty-three years, was referred for treatment of a mild rosacea.

Examination revealed the usual findings of rosacea. In addition, on the right cheek there was a small typical epithelioma which had been overlooked. The lesion was entirely classical in its morphology and was made up of a raised, rolled, pearly, translucent border with a scaly, depressed center. Had there been more ulceration or more crusting, the epithelioma probably would not have been overlooked.

Case XV.—Mr. E. C., a graduate student of twenty-two years, had been under treatment for several weeks for what was regarded as a coated tongue due to reversed peristalsis.

Examination disclosed a tongue which was coated with a thick, whitish, furry material. This coating seemed to be made up of innumerable filiform projections, closely packed together. Material from this coating was easily removed by a curet. The underlying tissues of the tongue were erythematous. No other part of the oral cavity and no other part of the body was involved.

A dietary history revealed no evident abnormalities.

The clinical diagnosis was moniliasis of the tongue (thrush). Microscopic examination of scrapings from the tongue revealed budding yeastlike cells which upon cultural study proved to be *Monilia albicans*.

The patient was completely resistant to the usual forms of local therapy as well as potassium iodide by mouth.

His tongue cleared rapidly, completely, and permanently upon administration of liver extract by mouth.

**Case XVI.**—W. C., an artist of fifty-five years, developed, two weeks prior to examination, a nonitching eruption involving penis, forearms, and right axilla. Patient was seen by a diagnostician, who did not recognize the case as one of Lichen planus and referred the patient for a dermatological opinion.

Inspection revealed numerous small, flat-topped, angular papules. Some of these showed the typical glistening sheen and others the violaceous tint characteristic of Lichen planus. In the right axilla there was a distinct row of flat-topped angular papules, running as if in the line of scratch. On the inner aspect of each cheek there were milky-white streaks. All of the morphological criteria for the diagnosis of Lichen planus were therefore satisfied.

Routine Wassermann, Hinton, and Kahn tests were all negative.

**Case XVII.**—R. D., an unmarried secretary twenty-two years of age, had been under treatment off and on for four years for what was regarded by her physician as pemphigus. From time to time large bullae would appear on her legs, arms, thighs, and feet. These ruptured easily and were very slow to heal.

The patient was referred for consultation. Inspection revealed on her legs and feet one large and several medium-sized bullae. Around the margin of each bulla there was a definite erythematous halo, which served to distinguish it from the pemphigus type of bulla which arises from the apparently normal skin. In addition, there were several typical, circinate, urticarial lesions.

The combination of bullous lesions and urticarial lesions was considered to be diagnostic of erythema multiforme rather than pemphigus.

A complete series of scratch tests was negative.

Treatment by means of elimination diets, calcium, hydrochloric acid, ephedrine, etc., was ineffective.

A tenth injection of aolan was followed by a severe vagotonic reaction consisting of extreme erythema and edema of face, numerous generalized urticarial lesions, diarrhea, abdominal cramps, weakness, and a sharp fall in blood pressure. She recovered very satisfactorily from this reaction, following adrenalin injections.

Since the above episode, the patient has remained completely free of all evidences of erythema multiforme for eleven months.

## SYMPOSIUM ON GASTRO-INTESTINAL DISEASES

The following clinics are included in this Symposium:

Andrew B. Rivers and Leslie A. Carlson: SOME EXTRAGASTRIC CAUSES OF DYSPEPSIA.

James F. Weir: PANCREATITIS.

Philip W. Brown: CONSTIPATION.

J. Arnold Bergen: THE TREATMENT OF DIARRHEA.

E. G. Wakefield: "SPASTIC COLITIS"; FUNCTIONAL DISORDER OF THE COLON AFFECTING YOUNG AND MIDDLE-AGED INDIVIDUALS.

Dwight L. Wilbur: VITAMIN DEFICIENCY DISEASES: THEIR DIAGNOSIS AND TREATMENT.

## SOME EXTRAGASTRIC CAUSES OF DYSPEPSIA

ANDREW B. RIVERS AND LESLIE A. CARLSON

---

A FRENCH writer referred to dyspepsia as the remorse of a guilty stomach. Although every physician knows that dyspepsia is not a disease in itself, it often remains the final diagnosis, and this frequently results in the dispensing of available measures which have been found to relieve belching, gas, or the various other symptoms that are included in the dyspeptic manifestations. Dyspeptic symptoms are usually the manifestation of nature's method of protesting against bodily abuses or are warnings of functional or pathologic disturbances of the gastro-intestinal tract. Nature does not confine her warnings to diseases of the stomach or even to organs utilized and concerned in the direct process of digestion. In this paper we are mainly concerned with the consideration of some of the more frequent and important extragastric diseases which manifest their presence by producing symptoms of dyspepsia. Almost any morbid process may herald its approach or announce its presence by causing some disturbance in the smooth, rhythmic process of digestion. Unfortunately, the degree or severity of the digestive disturbance is not necessarily an indication of the extent or gravity of the disease responsible for the symptoms. In order to appreciate this fact one need only consider the violent digestive disturbances experienced by neurotic individuals and compare these with the trivial disturbances of digestion caused by some extensive carcinomas of the stomach. Therefore, it is of the utmost importance to heed dyspeptic warnings as possible danger signals and to make every effort, especially in the presence of protracted and persistent disturbances, to ascertain the exact cause of any indigestion.

## SYMPTOMS OF DYSPEPSIA

Before proceeding into a more detailed consideration of the various causative factors of dyspepsia, it seems advisable to consider separately some of its more important symptoms.

**Pain.**—Pain is one of the most important and frequently one of the most baffling manifestations of disturbed digestion. This is readily understandable when one considers the mechanics of the production of pain in the gastro-intestinal and accessory tracts. In order to evaluate reasonably some of the painful phenomena experienced by dyspeptic patients, it seems advisable to review, at least briefly, the more important factors involved in the production of such pain. Painful impulses arising in the upper part of the gastro-intestinal tract may originate in the wall of the viscus, course along bundles in the sheath of the splanchnic nerves, cross over through the white rami communicantes of the thoracic nerves along the posterior roots of the spinal nerves, and thus may enter the posterior horn of the spinal cord. It is well to remember that painful impulses may also be conducted centrally through the sensitive cerebro-spinal somatic nerves, twigs of which supply the parietal peritoneum and many of the appendages of the posterior abdominal wall. The vagus nerves also contain some sensory fibers but it is doubtful whether these are very important in relaying painful impulses from the upper part of the gastro-intestinal tract to the brain. Lesions situated high in the gastro-intestinal tract, that is, about the cardia and esophagus, may send painful impulses to the brain through the phrenic pathways. Difficulty at once arises when an attempt is made to explain the genesis of pain from viscera which ordinarily seem practically insensible to the stimuli which produce pain on the surface of the body. All physicians have been present when extensive resections of upper abdominal viscera were performed under *local anesthesia* without serious complaint from the patient. An explanation of this paradox seems possible since it has been found that gastro-intestinal lesions can produce appreciable pain by way of fibers accompanying, if not part of, sympathetic nerves, providing an adequate stimulus has arisen in the viscus. This adequate stimulus is assumed to be an increase in pressure within gastro-intestinal segments, which results in stretching of the circulatory fibers of the viscus. It has been suggested

that in the stomach this spasm can be the result of hyperacidity which acts as a trigger mechanism that sets in motion spasm which in turn may constitute a stimulus entirely adequate to be appreciated as pain. Furthermore, muscular stretching could be incident to bombardment of peristaltic waves against an obstructing or partially obstructing segment anywhere in the bowel. This could be caused by organic obstruction, or by functional or sphincteric spasm of any circular muscle. There seems no doubt at the present time that spinal sensory nerves are of considerable importance in relaying impulses to the spinal cord, provided the lesion progresses beyond the confines of the intestines and invades neighboring tissues. Thus, as an example, the simple, clear-cut symptoms of uncomplicated peptic ulcer most likely would be visceral phenomena appreciated by means of afferent conducting mechanisms included within the sympathetic nervous system. With invasion of the tissues surrounding the intestines, warnings of the traumatizing effects of such invasion would be conducted through the nerves guarding these tissues, which would be branches of the spinal sensory nerves. In instances in which lesions are situated in the upper part of the stomach or in the esophagus, pain is not infrequently referred along the peripheral distribution of the phrenic nerve, thus producing pain in the neck or even in the tip of the left shoulder.

The diffuse epigastric distress that is almost universally associated with obstructing lesions of the gastro-intestinal tract, regardless of the position of such lesions, in all probability arises because of disturbed mechanics or disturbances in the wall of the viscus, which could be visceral phenomena that would be transmitted centrally along the sympathetic nerves.

In the progress of perforation to tissues surrounding a gastro-intestinal lesion, it would seem that the warnings of the traumatizing effects of such invasion would be conducted through nerves guarding these tissues, which would probably be branches of the somatic nerves.

Thus, it becomes intelligible how lesions even in distant regions, can indicate their presence by dyspepsia, since it is only necessary to produce disturbances in the mechanics of the stomach or upper part of the intestinal tract in order to produce an adequate stimulus such as spasm which may then be

interpreted as pain and relayed to the spinal cord along the fibers of the splanchnic nerves.

**Pyrosis or Acid Regurgitation.**—Pyrosis is a sensation of burning felt in the epigastrium or below the lower portion of the sternum. It is usually interpreted by the laity and by some physicians as evidence of excessive gastric acidity. Because of disturbed peristaltic activity the highly acid chyme is assumed to be regurgitated into the esophagus, the nasopharynx and the mouth, thus producing a sensation of heat in the epigastrium. This presumption is probably correct in many instances, although it is by no means always true. We have seen many instances in which patients regurgitated material which they described as sour and productive of a burning sensation, but chemical investigations of the gastric contents in these cases did not reveal any free hydrochloric acid. The reflux of acid chyme into the mouth is not necessarily indicative of hyperchlorhydria or of any disease, such as peptic ulcer, which is usually associated with increased peptic activity. Acid regurgitation occurs not infrequently in the presence of normal gastric acidity. These symptoms are not pathognomonic of any definite disease. Most frequently, in fact, they are the result of disturbances in peristaltic activity associated with errors in alimentation, or they are the result of functional diseases associated with reflex gastro-intestinal disturbances.

**Flatulence, Fullness, and Belching.**—Flatulence is a sensation of distention of the stomach and is usually felt under the sternum or throughout the epigastrium. This sensation, which is usually the result of an increase in intragastric pressure, is caused by an accentuation in the tonus of the gastric musculature. We have often been able to produce similar sensations involving the right upper abdominal quadrant or the hypogastrium by rapidly distending the duodenum or jejunum, respectively, with air or water. A similar type of distress very frequently results from an increase of intracolonic pressure or from hyperperistalsis associated with accentuated colonic irritability. The mechanism of distress in these instances is probably a splanchnic one, the adequate stimulus being produced by stretching of the circular muscle fibers within the gastrointestinal wall. In most instances, gastric flatulence is probably the result of swallowed air. Patients have noted that they

seem able to relieve their symptoms temporarily by belching: they have learned by past experience that if they are able to swallow air in sufficient amounts this will induce belching, which in turn will produce relief. Unfortunately, in many instances, the distention is not intragastric but rather to be found within the small bowel or the colon. Air-cribbing or aerophagia, therefore, results merely in an intensification of the distress. In many instances, flatulence, often associated with belching, is associated with functional disturbances. The loud, dramatic belching of the aerophagic, neurotic, dyspeptic patient is one of the oft experienced phenomena to which all physicians are exposed. Belching resulting from aerophagia is usually odorless, tasteless, or mingled with the flavor of the food which has recently been ingested. The belching occurring in chronic dyspepsias of an organic nature, particularly those associated with actual obstructive disturbances in the upper gastro-intestinal tract, usually has a bad odor. It may have the odor of hydrogen sulfide and is usually accompanied by other evidences of delayed emptying of the stomach or duodenum. Of the organic diseases associated with such symptoms, peptic ulcer and diseases of the gallbladder are the most important. It should be pointed out that the sensation of retrosternal fullness is not an infrequent accompaniment of coronary disease or cardiac decompensation. Esophageal disturbances incident to mechanical disturbances at the cardia also frequently manifest their presence by such symptoms.

**Anorexia.**—Appetite is assumed by many observers to be related to a sensation of gastric tonus. Ryle, in summarizing his views on the gastric sensations associated with appetite, suggested that these are in part a memory process and in part a local manifestation of efficient gastric tonus induced reflexly by the memory stimulus, by the more direct stimulus of seeing, smelling, tasting or swallowing food, or by some combination of these factors. He expressed the opinion that anorexia is a disturbance of motor function in which there is a diminished tonus or a pathologic rigidity of the gastric wall. He believed that prolonged fatigue is one of the more common causes of this symptom. He pointed out that profound emotion and prolonged worry may impair gastric tonus, probably through the medium of the sympathetic nervous system. During these cir-

cumstances there is often loss of sleep and physical rest, and thus fatigue at least may be a contributory factor. He suggested that in acute fevers and in chronic infections muscular tonus is impaired by the circulating toxins and he believed that the basis for anorexia was established in this manner. The loss of appetite associated with chronic alcoholism he attributed partly to the general effects of the poison on muscular function and metabolism and partly to the excessive secretion of mucus which inhibits normal stimulation of the gastric muscles and consequently the stimulation of appetite directly attributable to eating. It might well be assumed that in many other cases of chronic gastritis a similar etiologic relationship might obtain. The loss of appetite which is such a constant and pronounced symptom of carcinoma of the stomach is assumed to be the result of infiltration of the gastric wall by the growth. Ryle furthermore pointed out that in cases of leather-bottle stomach anorexia may be the only symptom and may occur independently of any extreme loss of weight, anemia, or any other factor such as pain or weakness. Anorexia, particularly that which affects elderly people and is unassociated with other systemic manifestations of disease, may indeed be a very important symptom and should invariably lead to thorough investigations of the upper part of the gastro-intestinal tract.

**Nausea and Vomiting.**—Nausea is characterized by a sinking or sick sensation in the epigastrium, usually accompanied, as Crohn has pointed out, by weakness, salivation, and dizziness. Crohn suggested that in the main nausea is probably a reflection of a state of irritation of the gastric mucosa, a sensory stimulation which is awakened in the afferent vagal fibers. He further suggested that the accompanying symptoms, such as dizziness, perspiration, and headache, are probably the result of a reflex general motor disturbance. Not infrequently, nausea may be produced among healthy individuals by disgusting odors, sights, and even by emotions. Ryle pointed out that oily and fatty foods and remedies which are known to inhibit gastric motility and secretion readily induce nausea, particularly among persons who have small appetites and hypotonic stomachs, and among those whose food requirements are low. Nausea is a common symptom in cases in which the value for the gastric acidity is low and the emptying time of the

stomach is prolonged. It is often found associated with chronic inflammatory conditions of the gastric mucosa. In many instances of functional disease, particularly in cases in which patients are of asthenic habitus, nausea is a frequent symptom which arises particularly when efforts are made to increase the amount of food that the patients should take. Nausea may result in vomiting, even in the absence of any unusual gastric residue or obstructive features. Many of the conditions which produce nausea may induce vomiting. The character of the material vomited is an important factor. If the vomitus includes only substances eaten several hours previously, the vomiting is no indication of the presence of an obstructing lesion. If, on the other hand, the material vomited includes substances eaten eight, ten, or more hours previously, the significance of the vomiting is very important. In order to ascertain whether or not the vomiting is an indication of obstruction, the use of barium or food motor meals should be advised. If there is definite evidence of residue when the stomach is aspirated nine hours after eating, this is a fair indication that actual obstruction exists.

#### CLASSIFICATION OF DYSPEPSIA

In their book, "The stomach and duodenum," Eusterman and Balfour classified dyspepsia, according to its etiology, as organic, reflex, systemic, and functional. This classification includes dyspepsia caused by organic diseases of the stomach and that caused by anatomic abnormalities involving the stomach. Inasmuch as this consideration will be limited to dyspepsia attributable to extragastric conditions it will be necessary to make some rearrangement of the classification of Eusterman and Balfour.

**Dyspepsia Attributable to Organic Disease of the Digestive Tube Contiguous to the Stomach.—***Esophagitis and Esophageal Ulcer.*—The most common disease of the esophagus is esophagitis. Vinson and Butt in a recent study reported the presence of esophagitis in 7.02 per cent of a series of 3,032 cases in which the patients came to necropsy. Definite symptoms occurred in 10.3 per cent of 213 cases in which a pathologic diagnosis of esophagitis was made. These authors expressed the opinion that vomiting is the important factor in

the etiology of this disease. They suggested that the anatomic structure of the esophagus makes it vulnerable to organisms of the oral cavity, and they were of the opinion that infections may occur through the lymphatic structures from the abdominal viscera. These authors also said that the most important symptom of esophagitis is a burning sensation over the lower part of the sternum. Pain and dysphagia also may occur and hematemesis occasionally develops. Clinically, it is difficult to distinguish esophagitis from esophageal ulcer which frequently occurs as an associated disease. An ulcer in the upper portion of the esophagus is usually traumatic. If the ulcer occurs near the cardia it may be peptic in origin. In approximately half the cases in which esophageal ulcer is situated at the cardia, the clinical history suggests the syndrome usually seen in peptic ulcer and the distress not infrequently is referred to the epigastrium. Dysphagia is a common symptom. A diagnosis of these conditions may be made by roentgenologic investigation, especially if an ulcer is present. Esophagoscopy usually will disclose the presence of inflammation or ulcerative disease involving the organ.

Carcinoma of the esophagus may manifest its presence by a distressing sensation of fullness or burning over the sternum. It frequently causes pain over the lower part of the sternum; the pain is definitely intensified during the act of deglutition. The diagnosis can usually be made by means of gastroscopic or roentgenologic investigation.

*Duodenal Ulcer.*—The organic disease which most frequently involves the tissues contiguous to the stomach and manifests its presence by dyspepsia is duodenal ulcer. One of the most characteristic features of the syndrome of duodenal ulcer is its periodicity. Attacks of variable duration alternate with periods of quiescence, which also are of variable duration. During the intervals between attacks, the ulcer may heal and at times may leave only a scar to indicate its situation. At times, an ulcer runs a fairly continuous course, without distinct periods of relief. Even in such instances, however, there are periods during which symptoms are mild. In the early stages of the syndrome of ulcer, the periods of distress are usually brief. Gradually, the period of quiescence becomes shorter. The attacks become more prolonged and frequently

more severe. The cause of the alternate periods of activity and quiescence is not entirely clear. Complications, such as hemorrhage or perforation, occasionally develop suddenly after a period of quiescence. Such complications at times develop during or following infections of different types. At times, heavy lifting, an alcoholic spree, or an unusually heavy meal may have preceded the occurrence of difficulties.

Reestablishment of the usual syndrome of chronic ulcer, with the characteristic pain, which is relieved by the ingestion of food or bicarbonate of soda, most frequently follows periods of prolonged unrelieved worry, unusual emotional disturbances, or catastrophe of any sort. Prolonged, intensive work associated with worry, or unusually fatiguing work, is blamed by many patients for their recurring difficulties.

The pain of uncomplicated gastroduodenal ulcer most frequently is situated fairly close to the median line and slightly above the umbilicus. The accurate localization of the pain is usually not possible.

Patients who have ulcer frequently notice that prior to the onset of their pain they experience a sensation of epigastric unrest, such as a slight rumbling or gurgling. This may stop, or in its place may come a sensation of hunger or occasionally a cramping sensation. These pains may be intermittent or they may be designated as a persistent cramp which does not become relaxed. The persistent pain, when very severe, is likely to be referred to the right or left upper quadrant of the abdomen, to the thorax, or to the back.

In cases of subacute or penetrating duodenal ulcer the pain is frequently referred to the right costal margin. The lesion then is probably definitely active, is progressing deeply into the wall of the duodenum, and is involving periduodenal tissues. With the development of referred pains in these cases, a change frequently occurs in other characteristics of the syndrome. The usual method of obtaining relief becomes less efficacious and periods of intermission become brief or entirely disappear. This deviation from the previous characteristics of the symptoms should suggest the probability of some change in the histopathologic structure of the lesion.

Although the pain caused by an uncomplicated peptic ulcer may be referred to the back, such a symptom, especially if the

tint to the scleræ. The value for the serum bilirubin ranged from 3 to 4 mg. per 100 c.c. The disease progressed rapidly. Within a few days the pain became more severe and opiates were required; nausea became increasingly distressing, the temperature became elevated and the rate of the pulse increased. Two days before death the patient vomited blood and passed tarry stools. Necropsy revealed a carcinoma involving the entire pancreas; there had been metastasis to the liver and two large ulcers had perforated into the duodenum.

Acute and chronic inflammatory lesions of the pancreas are extremely difficult to diagnose. The diagnosis of acute pancreatitis can rarely be made before operation. There may have been a history of previous attacks of pain in the upper part of the abdomen and vomiting which simulated gallstone colic, yet at operation or necropsy no evidence of disease of the gall-bladder or bile ducts may be found. The usual clinical picture consists of severe epigastric pain which appears suddenly and produces severe shock. The pain frequently is situated to the left of the median line. Muscular rigidity is absent but the pain is associated with tenderness and an indefinite resistance to deep palpation. Comfort has pointed out that the normal value for the activity of lipase, expressed in terms of twentieth normal solution of sodium hydroxide, is 1.5 c.c. for 1 c.c. of serum. In 95 per cent of cases of acute pancreatitis the values were considerably elevated.

Considerable confusion exists concerning the etiology and diagnosis of chronic pancreatitis. Pain is present in only about half of the cases, and when present it is hard to distinguish from that produced by peptic ulcer or cholecystitis. It may come on two or three hours after meals, is usually not severe, is frequently situated to the left of the midline, and may extend around the left side of the abdomen to the back or to the left shoulder. As a rule, administration of alkali does not produce complete relief. The passage of light, bulky, foamy stools which contain an excess of fat and muscle fibers is almost diagnostic. Glycosuria is present in a third to a half of the cases.

*Diseases of the Lower Part of the Small Bowel and the Colon.*—Diseases of the lower part of the small bowel and the colon usually are productive of some symptoms which suggest disturbances of digestion. Meckel's diverticulum, although

found in only about 2 per cent of all patients, contains heterotopic mucosa of the gastric type in about 20 per cent of instances. This may lead to the production of ulcerations, hemorrhage, or perforation. The indigestion which results may simulate the dyspepsia of peptic ulcer. At other times it may easily be confused with the signs and symptoms of appendicitis.

The following case illustrates the necessity of considering Meckel's diverticulum as the explanation for recurring attacks of indigestion.

A girl, aged eight years, had been subjected to an appendectomy because of abdominal pain and vomiting at the age of three years. Following this operation she had experienced frequent recurring attacks of abdominal distress. These attacks had become more frequent and she finally had passed tarry stools. Melena had been noticed on several occasions. Signs of partial intestinal obstruction had developed and laparotomy had been performed. At operation it had been found necessary to resect a portion of bowel because of intussusception. Before the patient had left the hospital she had had a recurrence of the abdominal distress. These attacks had continued and a diagnosis of "colitis" had been made. Treatment, which had been directed toward this condition, had brought about some relief and six weeks after the operation the patient had felt much improved. Two weeks before she came to the Clinic, however, she had noted tarry stools two to three times daily for four to five days. The passage of the stools had been followed by periumbilical pain. Operation revealed a Meckel's diverticulum with an ulcer at the base.

Vague and variable abdominal pains associated with tarry stools should always direct attention to the possibility of a Meckel's diverticulum, especially if the patient is a child.

Tumors of the small bowel and even tumors of the colon at times may cause physiologic alterations which are reflexly referred to the stomach. Early obstruction may be heralded by vague abdominal symptoms which may be considered as mild indigestion.

Regional ileitis, ileocecal tuberculosis, and colitis usually indicate their presence by varying degrees of indigestion. As a rule, questioning will elicit a history which suggests alterations in normal bowel habits and often reveals that the patient

has passed blood and mucus. In these instances the discomfort frequently is said to be referred chiefly to the umbilical region or to the lower part of the abdomen.

*Constipation.*—No discussion of extragastric causes of indigestion would be complete without adequate consideration of constipation. Patients who are constipated may complain bitterly of indigestion which might indicate serious "stomach trouble," and thorough roentgenologic and other examinations may be required to determine the true nature of the causative factor. These patients may complain of a sense of fullness, nausea, and vague abdominal pain. The pain usually is generalized, it occasionally is colicky in nature and frequently follows the course of the colon. Regulation of an obstinate constipation may cause a perturbing dyspepsia to disappear dramatically.

Hypersensitive patients, on the other hand, may appreciate normal physiologic processes more than does the average person. Many patients do not appreciate that the true criterion of constipation is the consistency of the stool rather than the frequency of bowel movements. Bowel habits vary among different people; some persons normally may have two bowel movements a day and others may have one movement every two or three days. Patients are frequently obsessed with the idea that they must have one or more bowel movements a day, and as a result they may fall into the enema or cathartic habit, which in itself may produce irritative symptoms.

The present-day habits of living no doubt are very important in the etiology of constipation. Concentrated foods, sweets, irregular meals which are eaten rapidly, nervous tension, lack of exercise, and inability to take the time to have a bowel movement no doubt are the most important causes. Many people ignore the call to stool and thereby dull the sensitivity of the nerve endings in the rectum. If this is repeated frequently, constipation may be the result. Dyspeptic symptoms, however, do not necessarily occur in such cases. As a rule, the next step is that the patients become concerned about this change of bowel habit and become "bowel conscious." They next resort to the use of laxatives and enemas as a time-saving method of having a bowel movement. They need only pick up daily newspapers or magazines to acquire plenty of free

advice on the dangers of constipation. They become thoroughly acquainted with the symptoms of auto-intoxication and become obsessed with the idea that they should have a bowel movement every day. They establish certain standards for this ideal stool and become "stool conscious." It is these patients who complain of a multitude of symptoms. They may complain of headache, dizziness, flushes, tiredness, insomnia, anorexia, vague abdominal symptoms, distention, and rumbling.

In such cases, sane habits of living, daily exercise, a balanced diet, and waiting for the normal physiologic evacuation of the colon may be all that is necessary to eliminate not only the symptoms but also the constipation. Unfortunately, once such patients have become acquainted with auto-intoxication and have established ideals for the perfect stool, they are never the same persons again.

*Hernia.*—Epigastric hernia is usually symptomless, but at times it may give rise to dyspeptic symptoms. There may be distress which occurs in the vicinity of the hernia. Catching of the mesentery or intra-abdominal viscera may cause twinges of pain. Flatulence may be an associated symptom. Inguinal hernia may give rise to nausea and vague abdominal pain or discomfort which most frequently is localized in the lower part of the abdomen. Unless careful physical examination is undertaken, the presence of herniation as a possible source of indigestion may be overlooked.

*Dyspepsias of Systemic Origin.*—In 15 to 20 per cent of all cases of dyspepsia the condition is reflex. One often forgets that the stomach may be the voice box of the neighboring abdominal organs; infrequently, it becomes the first organ to appreciate disease at a distance.

*Heart Disease.*—Disease of the heart deserves first mention if only to emphasize again the fact that the diagnosis of acute indigestion frequently gives way on further questioning to that of coronary thrombosis.

Heart disease not infrequently simulates an acute abdominal emergency. Patients frequently assume that symptoms are the result of indigestion when even a few cursory questions will make it clear that they have had an attack of angina pectoris. These patients may complain of pain which first appears, or increases in severity, after meals. Flatulence and fullness in

the epigastrium may be associated with the pain. These patients may not appreciate the effect exertion has on the production of the pain. It is not unusual for cardiologists to see patients who complain of diffuse pain in the thorax and upper part of the abdomen. This pain is associated with abdominal fullness and flatulence which are closely related to the taking of food and obviously are not related to exertion. It is difficult to convince these patients of the nature of their malady. The diagnosis in these cases is most frequently made from a painstaking history, with particular reference to the influence of exertion on the production of pain.

Myocardial failure, which is associated with congestion of gastric vessels, enlargement and congestion of the liver, and, at times, with ascites, may produce fullness, epigastric discomfort, belching, and anorexia, which are more distressing to the patient than is the shortness of breath.

In advanced cardiac failure the signs of the disease make the diagnosis clear. In the early stages of cardiac failure, however, before definite evidence of cardiac decompensation has become apparent, it may be difficult to make a diagnosis. If rest in bed or a restriction of physical activity results in disappearance of the symptoms, early heart failure should be suspected. This test is insufficient proof, however, to incriminate the heart because dyspepsia caused by other conditions may disappear after rest. Even though the heart is suspected, it is wise to wait for definite signs of cardiac failure before making a final diagnosis.

*Intrathoracic Disease.*—Intrathoracic diseases, such as basal pleurisy and tuberculosis, may produce symptoms referable to the abdomen. The extension of pain which originates in the pleura has led to many unnecessary operations for alleged cholecystitis or appendicitis. The acute pleural disease is usually recognized without much difficulty. This may not be true in cases of chronic or recurring pleural irritation. There are many instances in which the residua of an old pleurisy remain after a pulmonary infection. There may be no clinical signs of activity and roentgenologic examination may reveal only a pleural thickening or some elevation of the diaphragm, yet these patients will periodically notice abdominal distress which may simulate intra-abdominal disease. This occurs after

a period of prolonged overwork during which body resistance is depleted, or it may occur in the course of intercurrent infections.

With each recurring attack of pleural irritation the abdominal pain recurs. It may be extremely important to recognize this possibility in evaluating the cause of recurring vague abdominal distress for which no obvious intra-abdominal cause is demonstrable.

*Renal Disease.*—Chronic disease of the kidney with or without uremia may give rise to nausea, vomiting and symptoms of dyspepsia. In certain cases of prostatic obstruction and prostatic calculus the gastro-intestinal symptoms often are equal in importance to those referable to the genito-urinary tract. A careful history, thorough examination and essential laboratory tests usually clarify the diagnosis without much difficulty. We recently have been much impressed with the frequency of dyspeptic manifestations in cases of genito-urinary disease.

*Pelvic Disease.*—Pelvic disease does not, as a rule, produce symptoms referable to the upper part of the abdomen. The pain is usually in the lower abdominal quadrant. Nausea and flatulence may be associated symptoms. We saw recently a case in which the symptoms had suggested a recurrent attack of appendicitis; there had been leukocytosis, flatulence, nausea, vomiting, and elevation of temperature. An appendectomy had failed to produce relief. Drainage of a pelvic abscess which was performed later, was followed by prompt relief of symptoms.

*Hepatic Disease.*—Dyspeptic symptoms associated with ascites, enlarged liver, jaundice or hematemesis, alone or in any combination, should direct one's attention to the liver as the site of the trouble. Unfortunately, these prominent signs are usually late in their appearance. This is especially true in the compensated and preascitic stage of cirrhosis. Vague abdominal symptoms, such as discomfort, fullness and flatulence which occur at irregular intervals, may be present for months before the patient consults a physician. If a patient who complains of vague abdominal symptoms is a man who is past middle age and admits that he has used alcohol, and if examination reveals a slight enlargement of the liver, an epigastric

hernia, a hairless abdomen, and frequently a sallow or sub-icteric tint to the skin, one should suspect cirrhosis. Such tests as the van den Bergh test and the bromsulphalein test may be considerable help.

*Diseases Which Involve the Nervous System.*—Unfortunately, in a paper of this length it is impossible to deal with these diseases in sufficient detail. One need to pause only briefly to consider the complex mechanism of digestion and its intimate secretory and mechanical relationship to the sympathetic and parasympathetic nervous systems in order to understand how organic or functional disturbances of the nervous system may affect the digestive system. Dyspepsia may herald the onset of many of the diseases which involve the brain, the spinal cord, or the meninges. All physicians know that vomiting with or without nausea is an important symptom of an intracranial neoplasm. Careful investigation of the central nervous system, including ophthalmologic examination for choked disks and alterations of the visual fields, will usually enable one to determine the presence of disease of the central nervous system. We recently observed a patient who had been subjected to a gastro-enterostomy because of abdominal symptoms. Two years after the operation, which had failed to relieve the symptoms, a cerebral endothelioma had been removed. This had been the real cause of the symptoms. The gastro-intestinal symptoms which have recurred, erroneously had been attributed to malfunction of the gastro-enterostomy. The real cause of the symptoms is a tumor of the brain.

The crisis of locomotor ataxia may mimic many intra-abdominal diseases. This frequently is ushered in by a feeling of vague unrest in the upper part of the abdomen. Rumbling and gurgling occur throughout the abdomen. Pain may then develop and may rapidly become extremely severe. Nausea is extreme; vomiting not infrequently accompanies the pain. Often, there is a sensation of a band-like constriction encircling the abdomen. All of the symptoms may terminate rapidly without any subjective residual manifestations. At other times, however, the nausea and vomiting may persist for days; even the ingestion of small amounts of water may result in violent spasms of vomiting. The patient may become disturbingly dehydrated so that intravenous administration of fluids may

become necessary. At other times the attack is very mild and any of the mentioned symptoms in a minimal degree may be the sole manifestation of the disease. A carefully conducted neurologic examination will usually enable one to make a correct diagnosis.

*Pregnancy.*—It is not to be forgotten that one of the earliest symptoms of pregnancy is morning illness, nausea, and vomiting. The chief complaints of pregnant women as well as women who are passing through the menopause may be gastrointestinal in nature.

*Intoxications.*—Certain systemic intoxications, such as lead poisoning, alcoholism, excessive use of tobacco and coffee, and inhalation of noxious gases may cause gastric discomfort and even symptoms which suggest peptic ulcer.

*Alkalosis* which results from intensive treatment with alkalies may be heralded by anorexia, nausea, abdominal discomfort, distaste for milk, and later by headache, drowsiness, delirium, and coma.

*Endocrine Diseases.*—Certain patients who are suffering from various endocrine diseases may complain chiefly of dyspepsia. In the original description of Addison's disease, one may find the following statement: "The leading and characteristic feature of the morbid state to which I would direct attention are anemia, general languor and debility, remarkable feebleness of the heart's action, irritability of the stomach, and a peculiar change in the color of the skin." It now is possible to recognize the chronic stage of the disease, so well described by Addison, as well as the stage of crises which is characterized by anorexia, nausea, vomiting and diarrhea, circulatory collapse, and associated changes in the chemical composition of the blood.

It should be realized, however, that all the symptoms of the chronic phase of the disease may not be characteristic. Some patients complain chiefly of periodic attacks of vague indigestion which may be relieved by the ingestion of food or bicarbonate of soda. These symptoms may precede the anemia, languor and pigmentation. The patients may be treated for ulcer and such treatment may or may not produce relief. With progression of the disease the pigmentation is easily overlooked and during the attacks of nausea, vomiting and asthenia, pyloric

obstruction may be diagnosed. Some of these patients have learned to take unusually large amounts of sodium chloride.

Patients who have diabetic acidosis may complain chiefly of nausea, vomiting and abdominal pain. At times, the clinical picture may be so characteristic of acute or subacute appendicitis that in spite of the diagnosis of the acidosis (which is not always made) there is a temptation to do an appendectomy. Adequate treatment for the acidosis will quickly clear up the diagnosis. Failure of the patient to respond to adequate treatment probably means the presence of an acutely inflamed appendix. We saw one such case several years ago, but unfortunately the condition was diagnosed at necropsy.

*Deficiency Diseases.*—Gastric disturbances may precede the onset of characteristic symptoms of deficiency diseases, including pernicious anemia, sprue, and pellagra. Similarly, anorexia, sore tongue, indefinite gastro-intestinal disturbances not related to the ingestion of meals may be present for months before characteristic symptoms of pernicious anemia make their appearance.

*Migraine.*—A patient who has migraine may complain chiefly of nausea and vomiting, and occasionally he may complain of abdominal pain. These symptoms are more prominent in the mind of the patient than are the associated headache or such visual disturbances as scintillating scotoma. Careful inquiry will reveal that unilateral headache frequently is an associated symptom. Inquiry into the family history may reveal that other members of the family have had "sick headaches" or "bilious attacks."

*Allergy.*—Alimentary allergy is receiving confirmation in the literature as an explanation of some dyspeptic symptoms. One can become overzealous in this field and can waste valuable time on elimination diets before first ruling out other possible causes for the disturbance. There is no doubt that many people are allergic to certain foods. Symptoms may come on at once after the taking of foods or there may be a delay of several hours. We recall a doctor who had typical symptoms of ulcer, but who obtained relief after eliminating milk from his diet. A woman who was about to be operated on for cholecystitis volunteered the information that coffee caused a digestive disturbance. The elimination of coffee cured the chole-

cystic syndrome. Chocolate, eggs, wheat products, milk, strawberries and shell fish are the most frequent offenders, but almost any food may affect some people. If the patient keeps a food diary, the offending food may be readily recognized.

**Functional Dyspepsia.**—One is justified in making a diagnosis of a functional dyspepsia in about 25 per cent of all cases of dyspepsia. It can hardly be overemphasized, however, that this diagnosis should only be made after the exclusion of all other causes. Rather than place a stigma on these patients and in order to avoid an embarrassing situation for himself, the physician should keep constantly on the alert for further signs and symptoms that may point the way to another diagnosis. Many diseases in their early stages may masquerade as dyspepsia; therefore, a hasty diagnosis of a functional disorder may delay the recognition of the real trouble when definite signs and symptoms become manifest.

**Habit Dyspepsia.**—One of the most common varieties of dyspepsia is that resulting from improper habits of living and eating. A careful history will elicit the information that the affected patients not only eat too fast, too much, and at irregular intervals, but they are fond of highly seasoned foods, stimulating beverages, carbonated waters, coffee, fried foods, and so forth. They are frequently under high tension, smoke excessively, and keep irregular hours. The important diagnostic point in these cases is that the establishment of a saner way of living and regularity in hours, and the use of proper food cure the dyspepsia. The difficulty is that the relief of symptoms following the establishment of proper habits does not seem worth while to these patients, and they quickly return to their old habits of living. They are constantly seeking a new remedy or an easy cure, and usually have several "dyspeptic cures" in their homes or offices. As one patient said, he would rather live twenty years less, as he had been living with indigestion, than to live to a ripe old age in the manner in which he should live.

**Psychoneurotic Dyspepsia.**—This diagnosis is made after several complete reviews of the history, the asking of further questions, and an attempt to establish a more confidential atmosphere have failed to reveal the presence of organic disease. The dyspeptic symptoms complained of in these cases are only an abdominal manifestation of a disordered mental state.

It may be necessary to have the patients return to the office on repeated occasions. A relationship will be established between doctor and patient which will be more conducive to the tactful inquiry into certain intimate problems of the patient than that which was obtained at the first visit.

A past history of nervous breakdowns on the part of the patient or his relatives, a family history of insanity, marital disharmony, social conflicts, economic hazards, sexual problems, as well as the presence of an unstable emotional state are repeatedly denied until the patient has absolute confidence in the physician.

Eusterman listed the following characteristics as helpful in recognizing these patients: (1) The disturbance may be of long duration, yet complications or progression may be absent and the patient may be in a good nutritional state. (2) The symptoms vary in the region in which they appear; they are variable in degree and are frequently continuous. (3) There is lack of sequence which is characteristic of the majority of organic lesions. (4) The pain or discomfort, when present, is diffuse and often is referred unaccountably. (5) While the patient may complain bitterly of his disturbance or sensations during waking hours, the symptoms may be completely absent at night. (6) Intermittent digestive disorders are often coincident with, or follow, emotional stress. (7) Physical disability is frequently marked and is entirely out of proportion to the severity of the symptoms. (8) There is usually evidence of other stigmas of a psychoneurotic or hysteric personality.

These patients frequently are most anxious to have an organic basis for their complaints. They go from physician to physician until someone calls their disease a name which sounds important. They simply must have some subterfuge or some excuse for their disability or their complaints. Even though they may finally be convinced that their symptoms are functional, they are anxious that the family be left under the impression that there really was some basis for their complaints, as organic disease or the abuses to which they were subjected.

Finally, it must be admitted that the diagnosis of neurosis is a dangerous one. No one can deny that organic changes of a microscopic or biochemical nature may be present. The inability to recognize these changes or to measure variations

from normal physiologic activity does not mean that they do not actually exist. At least, it is safer to assume the possibility even though maintaining a confident and firm attitude toward the patient. No doubt many of the advances in the future will be directed toward establishing a definite organic etiology for these functional disturbances.

## PANCREATITIS

JAMES F. WEIR

---

OUR interest in this subject was stimulated by the statement of one of our colleagues who said that he thought a correct diagnosis had only infrequently been made in cases of pancreatitis. When one thinks of pancreatitis one usually thinks of a pretty serious and often fatal condition. The textbook picture is one of catastrophe. We feel that many of the cases do not belong in that category. It has often been said that the gallbladder is a frequent source of the infection that precipitates infection in the pancreas. In several of the cases we wish to present there was apparently little trouble in the gallbladder. There has recently been reported in the literature some change in opinion in regard to the methods of handling patients with pancreatitis, and also a number of studies on enzymes. It is for these reasons that we would like to present the following four cases:

**Case I.**—Dr. Foley: The patient in the first case, a man aged thirty-five years, in August, 1919, had had an attack of epigastric distress and dull pain in the right upper quadrant of the abdomen. This attack had been followed by jaundice. Cholecystostomy had been performed elsewhere, and the gallbladder was said to have been infected. The patient had made a good recovery. In October, 1919, he came to the Clinic because of continued pain in the right upper portion of the abdomen, and because of epigastric distress which had been worse three hours after meals and had not been relieved by food. Dietary management was advised. The patient improved and remained well until 1927 when he had two chills, with fever, epigastric distress, gas, and belching. Two days later he noticed some jaundice. This cleared after a few days. In 1928 the patient had repeated attacks of right upper ab-

dominal distress, chills, fever, gas, constipation and clay-colored stools. In November, cholecystectomy was performed, elsewhere. He improved for two weeks after operation, but the symptoms recurred. These attacks continued at intervals of one to four weeks. In March, 1931, a T tube was placed in the bile duct. The surgeon told him that the common duct was merely a fibrous cord. Fifteen days after operation an abscess of the liver developed and was drained. On June 10, 1931, another exploratory operation was carried out, elsewhere. The T tube was not removed. Subsequently, the jaundice disappeared and the stools became normal. The patient continued to have "sour stomach" occasionally and attacks of dull epigastric pain lasting two days.

In the spring of 1932, the patient had a mild chill, followed by fever which lasted only two days but reappeared the following September. This attack was associated with dark urine and jaundice. The condition cleared after a few days, but the patient continued to have some epigastric distress for which he came to the Clinic, October 26, 1932. At that time a roentgenogram of the thorax revealed marked irregularity of the diaphragm on both sides. Roentgenograms of the gallbladder, without dye having been given, and of the stomach and duodenum, were negative. The laboratory findings were as follows: galactose tolerance test, negative; serum bilirubin, 2.2 mg. per 100 c.c. (direct reaction); hemoglobin, 12.6 gm. per 100 c.c., and erythrocytes 4,030,000 and leukocytes 6,100 per cubic millimeter of blood. A diagnosis was made of intermittent obstruction of the common duct, the patient was hospitalized, and medical treatment was given.

On May 4, 1933, the patient returned to the Clinic and stated that he had been troubled with several attacks similar to previous ones; he had become considerably jaundiced just a few days prior to this visit to the Clinic. At this time the laboratory findings were as follows: hemoglobin, 11.5 gm.; erythrocytes 3,750,000 and leukocytes 3,600 per cubic millimeter; serum bilirubin, 6.8 mg. (direct reaction), and the galactose tolerance test, negative. Urinalysis gave negative results except that the urine contained bile. The diagnosis of intermittent obstruction of the common duct was again made, together with that of jaundice and secondary biliary cirrhosis.

Exploration was performed May 30 by Dr. Walters. The liver was found to be cirrhotic, grade 4. Every portion was involved and was covered with hobnail nodules. In view of this, and of the presence of bile in the duodenum, it was thought unwise to dissect the mass of adhesions in search of the common duct; a specimen of the liver was taken for biopsy and the abdomen was closed. The patient made an uneventful recovery and was dismissed June 24, 1933. He then remained fairly well until October, 1933, at which time there was recurrence of chills and fever, and of colicky pain in the right upper portion of the abdomen. The pain was projected through to the back and was associated with nausea, vomiting and fluctuating jaundice. These attacks occurred at weekly intervals. In August, 1934, he began to have diarrhea. He had from two to twelve stools a day; they were gray, were not greasy or foamy and did not float.

The patient returned to the Clinic March 7, 1935. He was hospitalized immediately because of severe attacks of pain in the right upper quadrant of the abdomen; morphine was required for relief. These symptoms and the diarrhea continued unabated until he left the hospital March 12. On this last visit he was found to be moderately emaciated, and a marked degree of jaundice and a fairly marked degree of clubbing of the fingers were present. He had a ventral hernia and enlarged veins on the abdominal wall. On deep inspiration the edge of the liver could be felt about 2 cm. below the costal margin. Moderate ascites was present. There was slight edema of the ankles. The blood pressure was 118 mm. systolic and 72 mm. diastolic. The laboratory data were as follows: March 7, hemoglobin, 8.45 gm.; erythrocytes, 3,130,000 and leukocytes, 2,900; March 9, hemoglobin, 8.1 gm. and erythrocytes, 3,120,000 and leukocytes, 4,100. There was slight macrocytosis. The serum bilirubin on two occasions was 12.0 mg. and 11.0 mg. per 100 c.c., with a direct reaction. The blood calcium was 6.7 mg. and blood phosphorus 1.5 mg. Blood sugar was 120 mg. per 100 c.c. The galactose tolerance test was negative. The serum protein was 5.6 mg. On several occasions the stools were positive for bile. The roentgenologist reported the stomach and proximal portion of the jejunum to be negative; the lower part of the jejunum and the ileum and colon had a fine,

dominal distress, chills, fever, gas, constipation and clay-colored stools. In November, cholecystectomy was performed, elsewhere. He improved for two weeks after operation, but the symptoms recurred. These attacks continued at intervals of one to four weeks. In March, 1931, a T tube was placed in the bile duct. The surgeon told him that the common duct was merely a fibrous cord. Fifteen days after operation an abscess of the liver developed and was drained. On June 10, 1931, another exploratory operation was carried out, elsewhere. The T tube was not removed. Subsequently, the jaundice disappeared and the stools became normal. The patient continued to have "sour stomach" occasionally and attacks of dull epigastric pain lasting two days.

In the spring of 1932, the patient had a mild chill, followed by fever which lasted only two days but reappeared the following September. This attack was associated with dark urine and jaundice. The condition cleared after a few days, but the patient continued to have some epigastric distress for which he came to the Clinic, October 26, 1932. At that time a roentgenogram of the thorax revealed marked irregularity of the diaphragm on both sides. Roentgenograms of the gallbladder, without dye having been given, and of the stomach and duodenum, were negative. The laboratory findings were as follows: galactose tolerance test, negative; serum bilirubin, 2.2 mg. per 100 c.c. (direct reaction); hemoglobin, 12.6 gm. per 100 c.c., and erythrocytes 4,030,000 and leukocytes 6,100 per cubic millimeter of blood. A diagnosis was made of intermittent obstruction of the common duct, the patient was hospitalized, and medical treatment was given.

On May 4, 1933, the patient returned to the Clinic and stated that he had been troubled with several attacks similar to previous ones; he had become considerably jaundiced just a few days prior to this visit to the Clinic. At this time the laboratory findings were as follows: hemoglobin, 11.5 gm.; erythrocytes 3,750,000 and leukocytes 3,600 per cubic millimeter; serum bilirubin, 6.8 mg. (direct reaction), and the galactose tolerance test, negative. Urinalysis gave negative results except that the urine contained bile. The diagnosis of intermittent obstruction of the common duct was again made, together with that of jaundice and secondary biliary cirrhosis.

Exploration was performed May 30 by Dr. Walters. The liver was found to be cirrhotic, grade 4. Every portion was involved and was covered with hobnail nodules. In view of this, and of the presence of bile in the duodenum, it was thought unwise to dissect the mass of adhesions in search of the common duct; a specimen of the liver was taken for biopsy and the abdomen was closed. The patient made an uneventful recovery and was dismissed June 24, 1933. He then remained fairly well until October, 1933, at which time there was recurrence of chills and fever, and of colicky pain in the right upper portion of the abdomen. The pain was projected through to the back and was associated with nausea, vomiting and fluctuating jaundice. These attacks occurred at weekly intervals. In August, 1934, he began to have diarrhea. He had from two to twelve stools a day; they were gray, were not greasy or foamy and did not float.

The patient returned to the Clinic March 7, 1935. He was hospitalized immediately because of severe attacks of pain in the right upper quadrant of the abdomen; morphine was required for relief. These symptoms and the diarrhea continued unabated until he left the hospital March 12. On this last visit he was found to be moderately emaciated, and a marked degree of jaundice and a fairly marked degree of clubbing of the fingers were present. He had a ventral hernia and enlarged veins on the abdominal wall. On deep inspiration the edge of the liver could be felt about 2 cm. below the costal margin. Moderate ascites was present. There was slight edema of the ankles. The blood pressure was 118 mm. systolic and 72 mm. diastolic. The laboratory data were as follows: March 7, hemoglobin, 8.45 gm.; erythrocytes, 3,130,000 and leukocytes, 2,900; March 9, hemoglobin, 8.1 gm. and erythrocytes, 3,120,000 and leukocytes, 4,100. There was slight macrocytosis. The serum bilirubin on two occasions was 12.0 mg. and 11.0 mg. per 100 c.c., with a direct reaction. The blood calcium was 6.7 mg. and blood phosphorus 1.5 mg. Blood sugar was 120 mg. per 100 c.c. The galactose tolerance test was negative. The serum protein was 5.6 mg. On several occasions the stools were positive for bile. The roentgenologist reported the stomach and proximal portion of the jejunum to be negative; the lower part of the jejunum and the ileum and colon had a fine,

granular appearance that might have been caused by food and barium.

DR. WEIR: This patient represents one of the catastrophes of disease of the biliary tract. The reason we are presenting the case is that since the patient's last visit to the Clinic diarrhea developed. We feel that this diarrhea is of pancreatic origin. The stools contained excessive amounts of fat, so-called steatorrheic stools. There was evidence of portal obstruction—edema, ascites, and distended veins in the abdomen. The persistence and severity of pain at the time of the last visit was possibly the result of an associated pancreatitis.

DR. GEORGE BROWN: Will you just restate the sequence of events as to where the pancreatitis stood in relation to what had been done in the past?

DR. WEIR: The patient had had four or five operations prior to exploration performed here in 1933, when, because of extensive cirrhosis and adhesions, the surgeon did not feel justified in dissecting down to the common duct. The patient possibly has a stone in the common duct, but cholangitis, cirrhosis and adhesions are certainly present and with pancreatitis can explain the patient's symptoms. Last fall diarrhea developed and there was loss of weight and pain, more severe than in the past. This is probably the time that pancreatitis developed.

DR. BROWN: Do you think the operative procedures and disease of the biliary tract are of secondary importance to the pancreatitis?

DR. WEIR: No. We cannot be sure how much the operations had to do with the patient's condition. If he had had a stricture or stone in the common duct, either could have played a large part in cirrhosis. On the other hand we know a patient can have cirrhosis with pain and without stones in the common duct. He can have attacks of colic, jaundice and so forth when the liver alone is diseased. In this case obstruction of the common duct probably was present and the liver and pancreatic changes were secondary.

DR. HELMHOLZ: He was relieved of jaundice when the fistula occurred, wasn't he?

DR. WEIR: Temporarily.

DR. HELMHOLZ: Did he have jaundice after that?

DR. WEIR: Yes. He has had it constantly for the last six or eight months.

**Case II.**—Dr. Foley: The next patient, a woman, twenty-eight years of age, had always been well until March, 1934. At that time a rather sudden attack of pain had developed in the right upper quadrant of the abdomen and this pain had been projected to the back and to the right shoulder. She had become jaundiced and had remained so. She had had chills, but not much fever, for about a week and had then recovered. She had had no qualitative distress from taking of food. She had continued to have an attack about once a week until December, 1934. There had been no jaundice during the time between attacks. On December 24, 1934, the patient's husband had noticed that she had a slight icteric tinge. Within the following few days she had become more jaundiced and had had several severe attacks of pain in the right upper quadrant of the abdomen.

Since that time the attacks had become more frequent, occurring every four or five days to a week. Throughout January and February she was confined to her bed. She had a fever, the temperature ranging from 99° to 103° F. The pulse rate was rapid through it all, ranging from 120 to 150 beats per minute. The jaundice fluctuated with the attacks. With each attack the pain was projected through to the back and was typical of a biliary type of pain. With this illness a mid-epigastric mass appeared, but it subsequently subsided. The patient had two tarry stools, but without having received medication of any kind which might have accounted for their appearance. She lost about 50 pounds (22.7 kg.). Her family physician noted glycosuria a few times. Other than that the history was negative. Examination at the Clinic gave negative results except for tenderness in the epigastrium grade 2, and slight jaundice.

DR. WEIR: The patient was obese. Her weight before she became ill was more than 200 pounds (90.7 kg.). She was younger, however, than the usual patient with acute pancreatitis, being at the time of admission only twenty-eight years old. She has had attacks of pain in the right upper quadrant of the abdomen similar to biliary colic which suggests the presence of

gallstones. Her referring physician sent along a letter describing her illness in January and February, during which time she had had severe pain requiring morphine for relief. The fever had persisted and a mass had developed in the epigastrium which he thought was an enlarged pancreas. She had been very ill at the time and had lost 50 pounds.

The history of a mass in the epigastrium, persistence of fever, pain and jaundice was practically diagnostic of acute pancreatitis. The patient had slight anemia and the serum bilirubin was 4.5 mg. The serum lipase was normal. Dye retention was graded 4; we would expect that with a history of jaundice over that length of time. The patient was operated on a few days later and the pancreas was found to be markedly enlarged and swollen. There were no stones in the biliary tract. The gallbladder was distended and edematous but was not otherwise diseased; it was removed and the common duct drained.

The prognosis in this case is rather uncertain. Whether prolonged external drainage of the common duct and keeping the patient's weight down and maintaining her in good health will help is problematic.

DR. BROWN: What is the mechanism of the periodic attacks of pain?

DR. WEIR: They are probably caused by acute exacerbation of the pancreatitis.

DR. BROWN: Is distention of the gallbladder due to edema or to backing up of bile?

DR. WEIR: I believe enlargement of the pancreas causes obstruction of the common duct, with secondary distention of the gallbladder. Edema plays a rôle in the pancreatic enlargement.

QUESTION: Do you think it is an infectious condition?

DR. WEIR: I think probably it is. Dragstedt did some work on this and found that *Bacillus welchii* was a common offending organism. Some men recommend the use of *Bacillus welchii* antitoxin.

DR. ALLEN: Why take out the gallbladder?

DR. WEIR: There may be some difference of opinion as to the advisability of that procedure.

DR. BROWN: How long do these attacks last?

DR. WEIR: This particular acute attack lasted two months.

QUESTION: Did the swelling last?

DR. WEIR: Yes. The pancreas is still swollen, although it has decreased in size so that it could not be palpated through the intact abdominal wall.

QUESTION: Have you made microscopic examinations in cases of pancreatitis?

DR. WEIR: Yes, but seldom as a surgical biopsy. Pathologic examinations are usually on necropsy material. An inflammatory reaction is found throughout the pancreas. Evidence of edema and fat necrosis may be prominent.

QUESTION: Does obstruction take place in the pancreatic ducts?

DR. WEIR: In some cases it does, but in others it doesn't.

QUESTION: How large did the surgeon say the pancreas was?

DR. WEIR: He said it was twice the normal size. It had decreased in size before operation so that we could not feel it. The patient was still obese; she weighed 160 pounds (72.6 kg.).

DR. FOLEY: One other thing I forgot to mention was that the concentration of blood sugar was 120 mg. per 100 c.c.

DR. WEIR: Glycosuria is frequently found in acute pancreatitis. In other cases a diabetic sugar tolerance curve may be found and, in later stages, a well-marked diabetes may appear.

**Case III.**—Dr. Foley: The patient in the third case, a man aged forty-three years, had first come to the Clinic August 8, 1932, with his wife. He had decided to be examined while he was here because for about two years he had had periodic attacks of burning pain in the epigastrium. These attacks had come on two to three hours after meals. Food and soda had given relief. There had been no pain at night nor projection of pain through to the back.

Examination revealed infected tonsils and some infected teeth. There was moderate tenderness in the epigastrium. Urinalysis gave negative results. The value for hemoglobin was 16.7 gm. per 100 c.c. of blood, and erythrocytes numbered 4,540,000 and leukocytes 14,200 per cubic millimeter. Analysis of the gastric content revealed total acidity of 44 units,

free hydrochloric acid of 32 units and a total quantity of 50 c.c. A roentgenogram of the stomach disclosed marked hypertrophy of the mucous membrane suggestive of gastritis. A tentative diagnosis was made of chronic gastritis. An ulcer type of regimen was prescribed and the patient was advised to have all foci of infection removed. He was then dismissed, and was asked to return in three months for further observation.

The patient returned January 23, 1933. At that time leukocytes numbered 11,000 per cubic millimeter. Analysis of the gastric content revealed a total acidity of 40 units, free hydrochloric acid of 28 units, a total quantity of 50 c.c. Fresh blood, grade 3, was present. A roentgenogram of the stomach again revealed marked hypertrophy of the mucous membrane; the duodenum appeared to be normal. The patient was dismissed but returned again October 12, 1933, at which time analysis of the gastric content revealed a total acidity of 52, free hydrochloric acid of 42 and a total quantity of 60 c.c. The patient had improved, but he still had periods of discomfort in the region of the epigastrium of two or three days' duration. This discomfort was followed by three or four days of freedom from symptoms. The results of general and roentgenographic examinations of the stomach were the same as on previous visits.

The patient was reexamined at the Clinic February 9, 1934, and said that the distress had remained unchanged until January 20, at which time severe, diffuse soreness throughout the abdomen had developed and had been associated with a temperature of 100° to 101° F. He was placed on ulcer treatment and, after three or four days, this trouble disappeared. The patient continued to suffer attacks of epigastric pain, occurring at 2 to 4 a. m. A roentgenogram revealed hypertrophy of the gastric mucosa and a perforating ulcer high on the posterior wall. The abdomen was explored February 12 by Dr. Judd, but he did not find any evidence of a perforating gastric ulcer. Marked pancreatitis and diffuse gastritis were present. The appendix was chronically inflamed and was removed. The gallbladder and liver appeared to be normal. The patient made an uneventful recovery from the operation.

The patient returned to the Clinic June 11, 1934, and stated that the pain had lost some of its relationship to meals and had been more constant. He had also noticed exacerbations of his

distress on two occasions following extraction of teeth. In May there had been some associated aching pain in the left lumbar region and on several occasions the stools had been light colored and the urine dark, without the appearance of noticeable jaundice. Erythrocytes at this time numbered 4,780,000 and leukocytes 7,600 per cubic millimeter. Gastric analysis revealed a total acidity of 34 units and free hydrochloric acid of 22 units, the total quantity being 50 c.c. The gastric content contained fresh blood, grade 1. The value for serum lipase (olive oil substrate) was 4 c.c. of twentieth normal sodium hydroxide per 100 c.c. A roentgenogram of the stomach revealed marked hypertrophy of the gastric mucosa. The patient was advised to continue on an ulcer type of regimen and to have his infected teeth and tonsils removed.

The patient returned to the Clinic in March, 1935. Since his previous visit he had had four or five attacks of epigastric pain and numerous occasions when the stools were light colored and loose. The value for hemoglobin at this time was 15.9 gm. per 100 c.c. of blood; erythrocytes numbered 3,870,000 and leukocytes 7,200 per cubic millimeter. Gastric analysis revealed a total acidity of 44 units, free hydrochloric acid of 30, and a total quantity of 30 c.c. The value for serum lipase was 7.9 c.c. of twentieth normal sodium hydroxide per 100 c.c. A roentgenogram of the stomach again revealed marked hypertrophy of the gastric mucosa, but there was no evidence of ulceration. Gastroscopic examination was performed by Dr. H. J. Moersch and nothing more than hypertrophied gastric mucosa was noted. The continuance of medical treatment was advised.

DR. WEIR: In June, 1934, the serum lipase was normal, about 2 c.c.; in March it was 7.9. That is the highest we have on record at the present. This is the interesting thing from the laboratory standpoint. You may ask what the significance of the hypertrophic gastric mucosa is. So far we do not know its significance. The question may also be asked whether the gastritis or hypertrophy had anything to do with the pancreatitis, or vice versa. I do not believe it did. I think the hypertrophy of the mucous membrane was a more or less incidental thing. The perforating ulcer found on roentgenographic examination probably resulted from the inflammatory

process in the pancreas having involved the posterior wall of the stomach. This case illustrates that type in which a great deal of pain is not manifested. The patient has had no jaundice. There has been some progressive loss of weight.

QUESTION: Does pancreatitis have any relation to focal infection?

DR. WEIR: I do not know.

DR. HELMHOLZ: I notice that twice you recommended removing the tonsils and teeth, but that nothing was done about it.

DR. WEIR: Here we are on debatable ground, and I do not know how you are going to settle the debate.

**Case IV.**—Dr. Foley: The patient in the fourth case, a man aged thirty-six years, was sent to hospital in an ambulance, March 9, 1935. He had always been in good health until twelve years previously when he had had cramps in the right upper quadrant of the abdomen followed by jaundice which had lasted for about a week. There had been marked distention of the abdomen for which castor oil and other laxatives had been given. The patient had been a fairly heavy drinker of alcoholic beverages for the last eight or ten years. He was a solitary drinker and always had liquor with him; he drank one or more pints of whiskey a day. Eight years ago he had begun to have periodic attacks of pain in the upper portion of the abdomen, associated with chills, fever, sweats and constant upper abdominal soreness. Each attack had lasted about four days, with one day of warning during which the patient had had anorexia and abdominal distention. The attacks had occurred about every six weeks. The pain had been felt first in the epigastrium; it had then been projected across the abdomen to the right and left and to the back, between the shoulders. It frequently had been sharp and severe and as many as three hypodermic injections of morphine in one hour have been required for relief. The fever, chills and sweats usually had continued for several days after the pain had disappeared. The patient had gained most relief from the attack by assuming a bent-over, crouched position. These attacks had continued until one year prior to his admission, had then stopped, but had recurred six weeks before his admission. Seven years before admission exploratory laparotomy

had been performed, elsewhere. A preoperative diagnosis of ulcer had been made but an ulcer had not been found at operation. The surgeon had noted that the pancreas was indurated and hard. The patient had gone to the hospital for three or four days with each of these attacks of pain, but no further treatment or investigations had been carried out in those seven years. The patient knew definitely that he had had diabetes mellitus for six weeks; his nurse stated that he also had had polydipsia and polyuria, and that he had lost weight for nearly a year. He had been taking 40 to 70 units of insulin daily for the last six weeks. His appetite had remained good. There had been considerable bloating and distention after meals. His bowels had moved regularly but the stools had been greasy, bulky, foamy and contained undigested food. He had lost 25 pounds (11.3 kg.) in the past year.

Examination revealed the patient to be undernourished, grade 2. The abdomen was not distended but was tense. No masses were present. The laboratory data were as follows: The urine was negative, the value for hemoglobin was 13.3 gm. per 100 c.c. and erythrocytes numbered 4,100,000 and leukocytes 7,900 per cubic millimeter. There was no evidence of macrocytosis. The concentration of blood urea was 20 mg. and that of blood sugar 163 mg. per 100 c.c. The value for serum bilirubin was 1.0 mg. and the reaction was indirect. Serum protein was 7.24 gm., and the albumin-globulin ratio 1.6:1. A test of hepatic function gave negative results. The hippuric acid test was negative, 5.22 gm. of hippuric acid being excreted. There was 4.81 mg. of serum phosphorus per 100 c.c. The value for serum lipase (olive oil substrate) was 1.5 c.c. of twentieth normal sodium hydroxide per 100 c.c. There was no activity of amylase and trypsin in the duodenal content either before or after administration of magnesium sulfate. The flocculation test for syphilis gave negative results. Roentgenograms revealed a normally functioning gallbladder. Many concretions were present in the pancreas. There was slight hypermotility of the small bowel; the mucosal pattern was normal.

DR. WEIR: Roentgenograms of the gallbladder gave evidence of normal function. It was found that there was some calcification in the region of the head of the pancreas. Further

roentgenograms were reported as giving evidence of multiple, extensive pancreatic lithiasis. The question comes up as to whether there are multiple calculi in the duct or not. After discussing this with the roentgenologists it was felt that extensive calcification and not stone in the pancreatic duct was present throughout the pancreas, the result of previous inflammation. Calcification takes place secondarily during the process of healing after fat necrosis. In this case exploration also was done; the gallbladder was drained; it was tense but there were no stones. The common duct was opened and no stones were found; a tube was put in for prolonged drainage. This case illustrates the development of pancreatic insufficiency after the development of pancreatitis, and that is manifested by the steatorrhea, loss of weight and by the more recent development of a diabetic syndrome.

QUESTION: Is that a common complication?

DR. WEIR: No, not very common. These patients are all young and pancreatitis is frequently considered as afflicting people a good deal older. Only one of the four was obese. I am going over some figures that Dr. Bannick has collected in regard to various points in a series of forty-seven cases. He divided them into hyperacute cases, thirteen, and acute cases, thirty-four. The hyperacute cases probably correspond to the old acute, hemorrhagic pancreatitis, with a rapidly fatal illness. Twelve of these thirteen patients died. In the thirty-four acute cases a diagnosis of pancreatitis was made correctly in only one case. It was suspected in four. Of the whole group of forty-seven cases, in twenty-seven the diagnosis was considered to be probable acute cholecystitis, in eight cases perforated ulcer, in four cases intestinal obstruction, in one case appendicitis, and in one case colic; in the remaining cases the diagnosis was indeterminate, and the distribution by sex was about equal. The patients' ages varied from twenty to seventy years. Seventy-nine per cent were obese. About 14 per cent had had previous dyspepsia but no attacks. Ten per cent had had no previous attacks at all.

In 85 per cent of the cases the attacks were associated with gallstones; some investigators give this figure as 45 to 50 per cent. It is the most frequently associated disease. The pain usually is sudden, acute, very severe and prolonged, and mor-

phine is frequently required for relief. The pain is situated in the upper part of the abdomen, in the right upper quadrant more frequently than in the left, although it was present in the left upper quadrant in a number of cases. The pain is projected posteriorly. Vomiting is common; it was present in twenty-five of the thirty-four acute cases. Tenderness is usually present. The rigidity which is present occurs largely in the right upper quadrant; it is different from that of perforated ulcer, lacking the board-like quality found in ulcer. Ileus was present in a few hyperacute cases and was marked; in the so-called acute cases it was not often present. The features of shock were most common in the hyperacute cases. Jaundice was present in thirteen of the hyperacute and in eleven of the acute cases. That symptom would help to distinguish pancreatitis from perforated ulcer. Glycosuria was found in 3 per cent of the hyperacute cases but in none of the acute cases. Fever was present in all but two cases. Leukocytes were increased to from 13,000 to 29,000, the usual increase being 17,000 per cubic millimeter.

So far as the studies on enzymes are concerned, we have not been doing any duodenal drainage to determine the enzymes except in the occasional case. We have been doing the serum lipase test, however, and a short time ago Dr. Comfort reported on 162 of these tests. One hundred and thirty patients were without known pancreatic disease, the value for lipase in 119 of these being less than 2 c.c. of twentieth normal sodium hydroxide per cubic centimeter of serum. In the thirty-two cases in which pancreatic disease was present, the value in 41 per cent of them was more than 2 c.c. There were twelve cases in which it was more than 3 c.c., nine of the patients having pancreatic disease and the other three diseases with which pancreatic disease often is associated: carcinoma of the gall-bladder, peritonitis and toxic hepatitis following pneumonia. Comfort has gone over subsequent cases in which the value for serum lipase has been determined and he has a series of more than 700 cases. His feeling is that a serum lipase of more than 2 c.c. is usually indicative of pancreatic disease.

As has been said, the highest value for serum lipase we have on record is 7.9 c.c. In the chronic cases apparently there is not much elevation. Elevation occurs in the acute

cases. So far as a study of the duodenal enzymes are concerned, the report of a committee at the last meeting of the American Gastro-enterological Association on the frequency with which the tests were used by members of the Association is of interest. They sent out 135 questionnaires and got replies from eighty-three members. Of these, thirty-seven members do not perform the tests. Duodenal drainage for trypsin was used by twenty-seven, for lipase by twenty and for amylase by twenty-three. So it is not used commonly even by members of the Association, the members of which are interested in pancreatic disease. The consensus of opinion was that in cases in which there was absence of pancreatic enzymes, the condition was caused by obstruction of the pancreatic duct. It was quite definite, also, that in sprue there was a decrease in pancreatic enzymes. The Committee felt that the difficulty in these determinations was pretty much a technical one. The question of the proper method of collecting specimens was a large factor.

Going back to our cases; so far as prognosis is concerned, it is uncertain. I think the first and last patients are near the end stage. They have pancreatic insufficiency, so far as digestion of food is concerned and the last patient has diabetes.

QUESTION: Do you think we are missing many of these cases?

DR. WEIR: I think we are missing quite a few of them. In subacute cases the condition is thought to be gallbladder colic.

QUESTION: Is there any difference in the pain?

DR. WEIR: Yes; in pancreatitis it is more persistent.

QUESTION: What do you say about the differential diagnosis?

DR. WEIR: It is very difficult to make a differential diagnosis. I think most of the men at the Clinic have not been successful in making one.

QUESTION: Did I understand you to say that in a series of thirty-four cases the diagnosis was correct in only one?

DR. WEIR: Yes. In the group of hyperacute cases there were a greater number of correct diagnoses.

QUESTION: Do they average better now?

DR. WEIR: I do not know. This is rather a flexible classi-

fication. As I have said, what Dr. Bannick calls hyperacute, is what was called the acute hemorrhagic case. Furthermore, I think the general tendency is away from surgery during the acute stage of the illness, such as in the second case we presented.

The physician at home found a mass but he did not advise surgery. The suction drainage apparatus is used for the stomach and glucose and saline solutions are administered intravenously; sometimes insulin is added to the treatment. These patients are treated as if they had intestinal obstruction. Wangensteen particularly advises that form of treatment. In the stages of suppuration it may be necessary to open and drain the pancreas, but that usually comes later, after the patient is over the shock of the original illness. The mortality in the acute stage is from 60 to 75 per cent. Those figures are pretty much for the hyperacute or the more severe acute cases.

QUESTION: Has pancreatitis occurred in children?

DR. AMBERG: We have never seen it and I have looked for it.

DR. HELMHOLZ: There are some cases of pancreatitis, with steatorrhea, in children, but they are very few and far between. Hess has reported some cases that had the picture of celiac disease, with marked sclerosis of the pancreas, but that was something different. Parker of San Francisco had one case. This is reported in the recent *Journal of Pediatrics*.

## CONSTIPATION

PHILIP W. BROWN

---

WHAT more can be said about constipation? The earliest records of man indicate that the two "C's," civilization and constipation, have carried along together to the present time. It is unlikely that the Ebers' Papyrus had as large a circulation among the ancient Egyptians as have our present-day papers, billboards, and magazines, but both early and recent writings stress the problem of constipation. The enemas and irrigations of our day have their counterpart in the enemas of ancient times, when the apparatus consisted of a leather bag or the bladder of an animal, to which was fitted a leg bone of a fowl or a small horn, as the enema tip. It is interesting that the early American Indians used a type of enema outfit similar to that recorded as having been used in early Chinese medical practice; this is, incidentally, another small item tending to support the idea that the origin of the Indian was the Yellow Race of Asia. Much later, in the seventeenth and eighteenth centuries, there were long, verbose diatribes on the use of the physick, the eccoprotic, and the purge. The season of the year, the position of the moon, the stature of the patient and so forth, had to be considered; yet these treatises are not more incentives to smile than are some of the more recent articles on auto-intoxication, spastic constipation, atonic constipation, constipation of infants, constipation of the aged and so forth. The enthusiasm for buttermilk, and later for acidophilus milk, have their counterpart in the writings of Paulus Aegineta, about 600 A. D., in which use of whey and sour milk was advised.

Hence, there is an ideal for which to strive, namely, a sensible understanding and a regimen for the management of a bodily function which has been faulty since the dawn of civilization. Many physical attributes, both external and internal, may be apparent in the species "*Homo sapiens*," yet

many of the recommendations for the management of constipation would indicate that he has been misnamed. One of the lessons hardest for both physician and patient to learn has been that, in spite of some similarities, the past, present, or future of no two people are exactly the same. The only possible exception might be in the case of apparently identical twins. Certain principles and working plans may be suitable as a start but the program must be altered to suit the individual; stock sizes of clothes may fit the bodies of many, but even then they are rarely as satisfactory as made to order clothes.

#### APPROACH TO THE PROBLEM

In view of this conception of constipation, it is obvious that the first necessity is evaluation of the individual and of what he means by "constipation." Commonly, he means a condition in which either bowel movements occur infrequently or the volume of the stools is insufficient. Some patients have become imbued with the idea that more than one stool a day is essential to good health. Others may have taken a laxative one or more times a week to "clean out"; evidently this is a heritage from former ages, for in Hindu writings of about 800 B. C. taking of a purge at regular intervals is advised. Still others have lived on a concentrated diet of meat, bread, tea, eggs, and so forth, and then become concerned that they pass only a small, dry stool every two or three days.

There seems little logic in endeavoring to classify types of constipation. The influence of early roentgenographic studies, in which the shadow seemed to indicate atonic or spastic states of the colon, has been as difficult to shake off as have the ideas originating in the same era, concerning dropped stomachs and dropped colons. The more inaccessible the organ, the more mystery that exists as to its function. How often the patient, with eyes dilated, tells of the bulky mass being propelled and churning its way like a battering ram through his sluggish bowel, or how often the woman tells how her tender colon has been scratched and rubbed by coarse foods, just as sandpaper would tear the face.

What is the physiology of the normal colon? There is enough sound knowledge to enable physicians to explain this

simply to their patients. Practically all of absorption of food has occurred before the residue reaches the cecum. In the right half of the colon, most of the water is then absorbed and the material begins to pass on into the left half of the colon in four to twelve hours, although even this figure varies widely. The left half of the colon is the storage space, or fecal reservoir, which normally empties in part at fairly regular intervals.

A sincere endeavor has been made to establish an upper limit to time, beyond which the interval required for passage of material through the bowel could be considered abnormal. Studies carried out by Alvarez and Freedlander indicate that there is a wide variation in the rate at which feces pass through the bowel. They used small beads and in further experiments measured the daily fractions of a barium meal excreted on successive days. About four days were required for excretion of 75 per cent of the beads or barium. In the same study, these investigators observed that if the colon was thoroughly emptied, either by a cathartic or because of diarrhea, there were no movements, or very small movements, for the next two or three days, or until the colon had filled again. It therefore is unphysiologic to empty the colon; normally only the terminal accumulation is pushed out at one time. This idea is important in the individual problem. Some colons are large, without megacolon actually being present; some absorb more fluid than others, leaving a drier, harder mass. The "wiring" of the colon, that is, the nerves and the stimulation mediated by them, differ with different individuals, and not only this but the control of the colon through the voluntary nerves also differs. The material from the ileum seems to be pushed into the cecum and ascending colon. At intervals in the day, mass movements occur which force the fecal content into the descending colon and rectum. This impulse, the gastrocolic reflex, seems often to be initiated by ingestion of food and when the impulse is fairly active, it explains why some people have a bowel movement after each meal. In a larger group, this mass movement seems to need to be repeated until sufficient residue has been pushed down to the rectosigmoid to initiate the desire to go to stool. If this desire is unheeded, some of the feces is carried back to the transverse colon. The neuro-anatomic trigger point in the rectosigmoid is not demonstrable. From experi-

ence, it is known that the rectum is normally empty except just before evacuation. Also, when the proctoscope is inserted into the rectosigmoid the patient usually announces that his bowels are going to move although the examiner can see that fecal material is not present at the moment. Other evidence that there is such a trigger zone is that if the rectosigmoid is resected, patients find it difficult to move the bowels, even though the channel is patent. This may likewise explain why, in some cases in which ileosigmoidostomy has been performed, constipation supervenes instead of the to be expected looseness of the stool. A physiologic, not an anatomic, block occurs.

#### SYMPTOMS OF CONSTIPATION

Are there symptoms attributable to failure to evacuate a certain amount of feces every day or two? Certainly, volumes have been written and advertisements have been poured forth on the dire result of faulty elimination. When all other factors have been eliminated, the sluggish colon has been blamed for arthritis, epilepsy, malignancy, and so forth. As this is being written (autumn of 1936), newspapers carry dispatches on the discovery of a cure for arthritis by means of a drug which will overcome or neutralize the poisons absorbed from a stagnant colon, evidently on the assumption that they are the cause of arthritis. There seems no doubt that most reasonable people, and who we or they are had best not be defined, insist they feel better, enjoy their meals more, and sleep better when their bowels move regularly. Closer analysis usually reveals that such people live fairly regular lives, that they eat, work, play, and sleep in a balanced, orderly fashion. They may work hard and deal with difficult mental problems but they, wittingly or unwittingly, have learned to spend only so much of themselves and always have something left over. When there intervene undue sorrows, irregular hours for sleeping and eating, or dissipation, so that there is nothing left over, then they begin to note irregular digestive disturbances and often sluggish intestinal action. All physicians know the occasional healthy, happy, competent person who defecates only twice a week, in contradistinction to the thin, nervous, frantic soul who purges or sluices his bowel one or more times a day with the idea that the bowel causes his sorrows. The extreme example of this

second type is the patient who exemplifies the "colon obsession neurosis," than which there is nothing more pathetic nor more exasperating. Likewise, is it not impressive that the patient with megacolon, who has a bowel movement only once a week, or even once in several weeks, has no particular digestive trouble? Their concern might be held to be more a cosmetic one, as the distended colon makes the abdomen more and more prominent.

Have we not tended to stress the symptoms of sluggish intestinal action, rather than to recognize it as merely part and parcel of the general social-economic struggle? It seems to me, in reading the ancient and medieval writings, and comparing our present-day patients with those described there, that constipation is an expression of disordered living, be it in the periods of famine of primitive peoples, when they had not sufficient food to make fecal residue, or be it exemplified by our modern peoples whose nervous systems are torn by the complexities of life. I have often wished that it were as easy to explain this to patients and to have them accept it readily as it is to inoculate them with the diagnosis of spastic colitis. More than twenty years ago an intelligent but very high-strung woman had been told by two of the most prominent surgeons of our period that she had spastic colitis. All these twenty years, enemas from one to ten times a day had been employed to wash out the poisons and to lave the lining of her supposedly diseased bowel. I had the temerity to suggest gradual discontinuance of the enemas and giving the bowel a chance. The reply was to be expected, "Well, I'd have you know Dr. — and Dr. — made my diagnosis, and if that is all you know there is no use wasting your or my time." The last part of her comment is correct; namely, it is usually a waste of the physician's time to "undiagnose" this condition for such a patient.

Although I feel strongly that constipation is a manifestation of faulty living, yet it is necessary to bear in mind that there are symptoms attributable to the condition. Most commonly, there is vague dyspepsia, flatulence, and back pressure from the bowel to the stomach. The appetite is poor and the tongue coated. This may be because the ileum has difficulty in forcing its content into the overloaded bowel, with re-

sultant increase in the frequency of reversed peristaltic waves in the small bowel. In some cases, this distention of the right half of the colon leads to tenderness in the right side, which has so often resulted in the diagnosis of chronic appendicitis and in unfairly crediting surgical operation with failure.

### DIAGNOSIS

All preceding remarks, and those in the rest of this article, are predicated on the fact that the patient does have constipation. The fact must be established not only by the patient's history but by thorough and conscientious examination. The occasional streaks of blood on the stool are probably attributable to hemorrhoids but until the index finger, or preferably the proctoscope, has revealed no cancer, one should withhold advice. Although constipation of many years' duration is fairly strong evidence of no organic narrowing, yet a barium enema is indicated if for no other reason than to be able to assure the patient that the channel, the main line, is open, even though it is not behaving properly. Especially imperative is the barium enema if the onset of constipation is of recent date. Again, there is the fear of missing an annular carcinoma if the physician too hastily blames change of diet or of water.

The vague dyspepsia may result from a growling gallbladder, from a duodenal ulcer, or from real chronic appendicitis although an acute attack that occurred many years ago may have been forgotten. Even though constipation is present, the inability to tolerate certain foods may not be attributable to the bowel but to these diseases.

In some cases in which the basal metabolic rate is low, elevation of the metabolic rate seems to lessen the constipation. But constipation is such a widespread difficulty that there are not sufficiently accurate data to justify its being considered that it is more prevalent among people whose metabolic rates are low than among others. Usually, elevation of the rate is not enough in itself to correct the difficulty and one must supplement with measures to combat the constipation. The symptoms of fatigue, nervousness, coldness, and so forth are more likely to be the causes of the main complaints, and not the constipation. Although many anal diseases may result in constipation, yet by no means do they always so result. Deep-

seated perirectal infection, anal cryptitis or fissure, or tender, swollen hemorrhoids may produce anal spasm, with semi-voluntary restraint to movement of the bowel in an effort to protect a sore place. This anal disease may all but prevent correction of the constipation until it is treated. Sometimes it may be difficult to demonstrate on the particular day of examination, that there is much anal disease, but to heed the history and to seek the conservative, intelligent treatment recommended by the expert proctologist has been the key to correction of the constipation. To go farther afield and to discuss severance of abnormally large or heavy valves of Houston is more in the field of the proctologist than in mine, although my opinion is that such a procedure is of little or no value.

#### TREATMENT

To the point of annoyance, it is imperative to reiterate the admonition, "Treat the patient and not the constipation." It always smacks of the magician to pull out of the desk drawer a sheet of paper printed months ago and gravely to pass it to the patient who graces the office at the moment. As if the regimen had been carefully planned many months in advance and would be just the thing! Oddly enough, it may reasonably fit the case and the patient may be pleased with the results. It is much more personal, more intelligent, and more practical, however, to consider the patient as an individual. It is no sin to have material on hand from which to choose and then to apply it properly but it is not wise to distribute handbills. A visit with the patient may reveal that the regularity of intestinal movement was first disturbed when attendance at college began, after the first baby arrived, when it was necessary to get to the office or to school after a hurried breakfast, and then to dash to beat the clock, through all walks of life. When the teacher or secretary reports that no toilet room is available on a certain floor, or only one for many, the physician ponders whether he should turn plumber or run an employment agency which promises adequate toilet facilities with each job. With active, healthy children, after once they are housebroken, there is seldom much trouble. A few children seem to begrudge the time to defecate and prefer to squirm rather than hurry when the desire to go to stool is felt. This may result in fecal im-

paction which must first be relieved and then the child must be more carefully watched. At the other end of the road is the elderly person who has slowed up, who takes less exercise than before, whose intake of a none too laxative diet has become decreased, whereas his diet was adequate as he formerly carried on. It is in this elderly group of patients, however, that excess bulk may produce large fecal impactions in the rectum.

While the background antedating the physical phases of life is considered first by the physician, yet first in the patient's mind may be any one of many worries. The physical, and especially the nervous, drain of the social-economic struggle is the fuel which is added to the fire in the anxious mind. The patient does not reason; he merely conjectures and suddenly he is sure that the impossible is true. Perhaps a neighbor or relative recently has been operated on for cancer of the colon, and the mere proof that he has no cancer may so relieve his mind that he no longer is concerned about his constipation, "if that is all it is."

The most difficult phobia is that of "auto-intoxication." I have often longed to sentence the inventor of that term to a hundred years of hard labor, consisting in his being consulted by all his disciples. More or less to the disgrace of physicians we have been too vague, too apparently callous to the complaints of these patients and they have sought sympathy and treatment from colon-slucers and the like. Some people cannot and will not be told and perhaps they might as well be allowed to pursue their own sweet will as to have the physician struggle to convince them. When a patient comes for treatment with his diagnosis established, an all but impossible situation is created at the outset. However, most people are willing to heed an opinion if they have been impressed by the sympathy and thoroughness of the physician. Alvarez approaches the problem with this explanation: "It has been well proved that, even in health, bacteria are constantly going through the intestinal mucosa; most of them are stopped in the neighboring lymph nodes, but some go on through into the liver and perhaps even into the general circulation. This passage of bacteria into the blood stream takes place more easily after purgation and in the presence of diarrhea, when holes are opened up

in the mucous membrane and when most of the bacteria in the bowel are living and virulent. In the presence of constipation the feces are so solid and dry and so lacking in nutriment that most of the bacteria die. Furthermore, it is obvious that little absorption can be expected from solid masses of fecal material. It is helpful to point out to an intelligent patient that few of the poisons that are known to be formed in the bowel can pass unchanged into the portal circulation. Most of them are stopped or chemically altered in the wall of the bowel, and those that get through are likely to be destroyed or changed in the liver or in the capillaries of the lung. Furthermore, any toxin that can get past these several filters must trickle into the general circulation so slowly and in such small doses that physiologic effects cannot be produced. Finally, the physician can assure the patient that there is no reliable evidence to indicate that anyone ever suffered serious injury to the brain or any other part of the body on account of constipation. Anyone who has seen many children and youths with Hirschsprung's disease, with the huge abdomen containing several liters of fecal matter, and yet with a clear skin and no complaint of headache or arthritis or hypertension or epilepsy, must have marveled at the efficiency of the mechanism with which we are endowed to protect us from the absorption of toxic material."

**Food; Diet.**—This has proved the great playground for the unethical food-chemist and dietitian, for the skillful advertiser who is in business to sell his product, and for the sleek individual with a "San Michele" practice. Oddly enough there is often much that is true in even the weirdest food program. It has been difficult for physicians to convince themselves, let alone patients, that not all bowels can be loaded with foreign bulk or that not all people must eat only carefully strained food. Puréed foods, or extra loads of bulk, are proper but must be passed on for each person. One patient may tolerate a fair amount of raw fruits and vegetables; another is more comfortable with most of these articles cooked. Physicians have been willing to recognize that a food may produce a severe gastro-intestinal upset but there is no reason to insist on only raw foods, or only cooked foods, or only puréed foods. Just as the person who recently was an invalid has not yet re-

gained his physical strength, so the patient who has held to a limited slop diet has not the tone for his bowel to accept an overload of roughage.

The ideal of an adequate, well-balanced variety of foods which will meet the need of the body for protein, energy, minerals, and vitamins must be sought. Individual hypersensitivity to one food may not disturb the program but if too large a block of foods is excluded, there must be temporary inclusion of the necessary vitamin concentrates. As the strength and resistance of the patient increase, his ability to tolerate a wider variety of foods is commonly observed. The most frequent omission from the diet of the adult is milk, whether the omission is attributable to actual intolerance, to mere dislike, to fear of gain in weight, or to the belief that milk increases constipation. I see no need of forcing the issue but I do believe that adequate intake of calcium is essential to smooth metabolism and that calcium should be supplied in powders or tablets. The presence of a reasonable amount of fat in the diet tends to make a bulkier, softer stool. Here, again, the problem of obesity may interfere but if it does not enter the situation, generous amounts of cream and butter are advised. Especially helpful is the daily intake of the old, old remedy of three or four tablespoonfuls of olive oil. If the patient has been on a very bland and restricted diet, the sensible, although gradual increase to a normal program of eating probably will increase the sense of abdominal distress and indigestion. If this is mentioned in advance and courage urged to bear with it, there will be less tendency for the patient to become too easily disheartened.

**General Program.**—The following points may serve as guides to treatment:

*Habit.*—In view of civilized customs and the necessity of regard for others, it is usually necessary to have a regular time for the bowel to empty its residue. Neglect of the desire to go to stool often is the first step in the production of constipation and the desire must be regained. The majority of normal people tend to have a movement shortly after arising or after breakfast. But if the day is started with a rush and flurry the bowel is given no chance to function.

*Nervous Tension.*—This great problem of life, and also the

## CONSTIPATION

desire for so-called progress, takes part of its toll in form of the habit of constipation. Under mental and emotive stress, there seems to be an actual clamping down of the bowels. In a few cases, added stress makes for the opposite state, diarrhea. When one's life is, as has been noted in the preceding paragraph, a frantic, hurried, harassed dash from morning perhaps late at night, it is logical that the nervous tension increases, and often constipation supervenes. Although many patients will strive honestly to reestablish the habit of regular movement of the bowel, yet they are in such a constant state of nervous strain that they merely "go through the motions" and cannot relax. Maimonides, a famous Jewish physician of the twelfth century, wrote as follows: "If a man keeps himself busy and tires himself out and then relaxes and keeps his bowels open, he is never sick."

*Exercise and Relaxation.*—Exercise, in the sense of physical activity and relaxation, is often lacking and so the need of maintaining a reasonable muscular tone has a definite place in the regimen. However, exercise alone is not the only thing, as is obvious from the large number of active workers, such as farmers and laborers, who are constipated. Nevertheless, the sedentary worker, who lives chiefly by his mental processes, is more likely to be constipated than his brother who lives by his muscles.

*Food and Fluid.*—The program of eating has been discussed. As to fluid, it is surprising to find how many people, especially women, will drink only two or three glasses of water a day. Explaining that water is absorbed in the large half of the colon to supply the general bodily needs, and that a too dry an intake will result in a drier fecal current moving into the left half of the colon, will encourage the patient to take sufficient fluid: he should take about 2 quarts (2 liters) a day, and more if there is excessive sweating. Other beverages may count toward the 2 quarts. In some instances the thought that discontinuance of excessive drinking of tea helped materially in restoring normal intestinal action to other stimulants, coffee, alcohol, and tobacco, it is doubtful if they directly increase constipation, although their influence through stimulation of the nervous system may be a factor. It has long been noted that the first smoke of the morning may serve to stimulate the desire to go to stool.

*Artificial Aids.*—These include drugs; bulky substances, enemas, and suppositories. These will be treated separately in the following section.

*Evaluation of Mechanical Aids.*—Among the early writings of man, as in the Ebers' Papyrus, for instance, is found advice about drugs for constipation. This work was written about 1500 B. C. and in it are recorded items known fully back to 3500 B. C. Fifteen times mention is made of castor oil; also aloes, oil from seeds, figs and sweet beer are mentioned. Hippocrates devoted attention to the laxatives but urged that they be as mild as possible. The early American Indians knew of the saline waters of mineral springs, and in California they knew of cascara. Francis Bacon wrote, "I commend rather, some diet for certain seasons rather than frequent use of physic except it be grown into a custom. For these diets alter the body more and trouble it less."

A detailed description of laxatives can be found in the books on pharmacology. As to their use, no set rule is sensible. Obviously, there is no need for drugs if the patient obtains results by the previously discussed regimen but if the patient is having a struggle, it seems no great crime to use one of the simpler drugs. How often one is asked, "Now, what is the best laxative?" My reply is that there is no such thing but if our bad habits have established a need of artificial aid, the patient should use that which accomplishes the result with the least possible general disturbance. I have preferred simple magnesia, fluid extract of cascara, or senna. Rather than whip the bowel with a single maximal dose, division of that amount into three portions and taking one of the portions after each meal, seems to give the extra push, as well as making it easier gradually to decrease the need for the drug. So often it has seemed more sensible to supplement the general regimen with divided, small doses (10 to 30 drops) of cascara after each meal, than to make a willing but miserable patient fight without help, probably after an enema-physic diet struggle of months or years. Especially for older people the little chemical irritant seems to be practical. Dr. W. J. Mayo said to a patient, "I can't see that taking a little physic is going to do you any more, if as much, harm as filling your stomach and bowel with a lot of rabbit food." When drugs are prescribed, it is with the

idea that they are merely crutches to help until the good habit replaces the bad one. It should be stressed that laxatives are no more a cure for constipation than are sedatives cures for "nerves" but both are valuable if intelligently used.

Belladonna has had first place for many years to relieve spasm. The actual evidence on which its use is based is so meager that I see no need to use it; the chances of intolerance to the drug developing are probably greater than the chances of any actual benefit.

Next in mechanical aids arises the question of enemas and how the great and near-great have flung that question back and forth. From the time of the bladder with its horn or bone tip to the time of the stupendous, expensive colon-sluicing machines, there has waged much clamor. As with laxatives, enemas are merely artificial, transitory aids in the correction of a bad habit. They are not cures, irrespective of the solution used. Nor is it likely more heinous to use an enema than it is to use a simple laxative. But again, emphasis must be laid on merely tiding over until the real factors can be more fully corrected. It seems futile to debate laxative versus enema; both are theoretically wrong but practically, whichever causes the least annoyance and is the simpler for the patient who must use a crutch it seems logical to me to use it. Wise Paulus Aegineta, in about the seventh century, wrote, "Clysters must not be repeated constantly lest nature, becoming accustomed to these things, should forget to perform the evacuation spontaneously." Certainly my opinion is not original and I am not sure whom Aegineta may have quoted. As to what kind of enema to use, I suggest warm physiologic saline solution (1 teaspoonful of salt to the pint). This is the least irritating solution. Allowing a pint to run in slowly, repeating if necessary, usually will prove effective.

Oils have been in vogue for centuries. The ancients used oil from various seeds or fruits which they prescribed either for oral administration or, if the stools were dry and hard, for administration by enema. Our era has added mineral oil which, of course, is undigested and merely slides through as a lubricant. In many cases, just this much artificial aid, a "swig" of oil at bedtime, gives excellent results. In other cases, it seems to cause indigestion or may trickle on through the bowel

without mixing with the feces. Emulsifying the oil with agar tends to overcome this objection but these products are expensive. Although olive oil is largely digested and absorbed, yet its oral administration long has been helpful; barring obesity or intolerance, I prefer a trial of it rather than of mineral oil.

Of recent, well-advertised origin is yeast, and there is no doubt that ingestion of yeast may give the extra push. In my experience, it fails oftener than it succeeds. Certainly it is harmless enough to try. There is no question of the changes that occur in the digestive tube when the diet is deficient. Some people may have coasted along on just a subthreshold margin which the yeast may correct. Bread dough, mixed with milk and honey, was recommended by the early Egyptians; maybe the bread dough is the first suggestion of the use of yeast; again we are 4,000 or 5,000 years behind!

Buttermilk and acidophilus milk have had their advocates in great waves, both scientists and advertisers. As to the latter, charity and not caustic comment is due; with 70 to 80 per cent of the population more or less constipated, there is a big group for advertisers to reach. I am convinced that many people have felt better and that their bowels have acted more regularly if they drank one or another of these milks. Whether they merely increase the fluid and bulk, or whether there is some bacterial action, I do not know. The fact that a good growth of *Bacillus acidophilus* in the bowel can be obtained by ingesting an ounce of milk sugar, just as can be obtained by drinking a quart of the milk, without seeming to improve constipation, has led me to doubt the great value of the bacterial change. Also, discontinuance of ingestion of the milk or milk sugar results in prompt return to the former level of the *Bacillus acidophilus* in the stool. Surely there is no objection to *Bacillus acidophilus* and if it helps, fine!

What about bran, various seeds, vegetable mucins, agar, and so forth? Most physicians now agree that people have gone far beyond the bounds of common sense in the manner in which they have poured foreign, insoluble stuff into the digestive tube. Granted, indeed, many people have been able to tolerate, and their intestines have functioned better with, this wadding, but for one of them there must be five, probably fifty, to whose

distress it merely has added. Again to quote Dr. W. J. Mayo: "It is bad enough to stuff on rabbit food without packing your bowel full of sawdust." Some physicians feel that it is unwise for whole wheat cereals and breads to be routinely included in the diet. Again, if any of these things help there is no argument but I do not recommend them as a rule. Rectal masses, the size of a large grapefruit, may occur from use of bran or vegetable mucins, particularly if people are elderly. If these substances are used at all, they should be taken in only small doses, and later it should be ascertained that the stuff is not packing in the rectum, even though the patient may be having daily movement of the bowel. In my experience, plain granular agar has been the least objectionable form in which to supply artificial bulk and if bulk must be added by means of this substance, to use it in doses of 1 to 3 teaspoonfuls with each meal.

Sometimes the physician is confronted by the desperate patient who actually begs for an operation, omitting, of course, correction of an anorectal pathologic condition. Many physicians have seen patients who have undergone right hemicolectomy, fixation of the mobile cecum, "tacking up" of the fallen transverse colon, or even ileosigmoidostomy, and still have constipation. I am opposed to any of these procedures to correct constipation; they occasionally have succeeded but in the majority of cases they have failed and in what a state those patients are! Possibly something may be worked out in the field of neurosurgery, although the results in cases of megacolon are not always successful. As yet, this must remain in the field of the experimenter.

**Constipation in Disease.**—Constipation is often a troublesome symptom in many diseases. In 200 A. D. a Chinese physician urged that only enemas be employed for the constipation of severe intestinal fevers (typhoid fever), no doubt from knowledge of patients dying after taking a purgative.

In pneumonia or in any illness which forces the patient to his bed, restriction of food, lack of activity, and possibly of greater importance the effect of toxemia on the nerve centers, create the difficult symptom of constipation. The use of various enemas, the type of which will vary with each locality, may suffice. Simple glycerin suppositories occasionally are effec-

tive. Hot abdominal stupes, if not too heavy, or the electric pad have seemed helpful, possibly more because of psychologic than the actual physical effect. Recently I have been impressed by the use of short wave diathermy over the abdomen; this may result in emptying of the bowel. It should be needless to caution against laxatives when one is not sure that there is no actual intestinal obstruction. Present records on appendicitis certainly show that the advice not to give purgatives to patients who have abdominal pain still will bear loud repetition. Hypodermic administration of pituitrin, acetylcholine, eserine, and so forth should be employed only after failure of other methods. Use of these drugs is not without danger and much caution and judgment must be exercised in their employment.

### CONCLUSION

Constipation is age-old and has been known of from the dawn of civilization. It is a habit and an expression of disordered living, physical or emotional; and usually both. It should be approached and treated as an error in living and not as a disease. The several thousand years' accumulation of advice, which is now greatly enhanced by present methods of communication, have done more to confuse than to help. Many present ideas, "notions," have their roots in antiquity and this knowledge should broaden our common sense approach to the problem. As with any other condition or with any disease, the patient should be studied and treated as an individual and not as just another case. And this is difficult to do!

## THE TREATMENT OF DIARRHEA

J. ARNOLD BARGEN

---

ONE of the most common, and often very distressing, symptoms of human disease and behavior is diarrhea. To consider its management under this broad title presumes delving into all manner of bodily dysfunctions. In general, it can be said that there are those conditions in which the symptom diarrhea is associated with disturbances outside of the intestine and those in which diarrhea is the result of disease of the intestine. Persistent or recurrent diarrhea may or may not be of serious moment, but its cause should be searched for in each instance with the greatest care. A most thorough investigation of each case of diarrhea is necessary to establish it as a symptom of a general bodily disorder or of local disease. Obviously, a thorough search of the digestive tract is in order in each case. In the main, it can be said that when diarrhea is the result of disturbances outside of the intestine the treatment is largely symptomatic or at least directed to the alleviation of the condition in which diarrhea is only one of the symptoms. This observation simplifies the story of management considerably. The conditions which may cause diarrhea are listed in the Tabulation. It is apparent that the diarrheas associated with conditions outside of the intestine are the result of reflex disturbances of intestinal function. It also follows that all the functional disorders, whether local or systemic, may be grouped together to simplify the study of their management.

On the other hand, all organic intestinal disorders must be considered individually for adequate therapeusis. It has been suggested that a real diagnosis cannot be made in even half of the cases of diarrhea. One must not confuse, however, the cause of diarrhea with the mechanism of its production. Even though the latter might not be explained in a given functional disturbance, the diagnosis may still be correct. The important

## TABULATION

## CONDITIONS ASSOCIATED WITH DIARRHEA

1. Systemic disturbances:
  - (a) Nervous diarrhea.
  - (b) Allergic diarrhea.
  - (c) Food poisoning.
  - (d) Trichinosis.
2. Metabolic disorders:
  - (a) Hyperthyroidism.
  - (b) Uremia.
3. Functional gastro-intestinal disorders:
  - (a) Irritable colon, unstable colon or "mucous colitis."
  - (b) Gastrogenic diarrhea.
  - (c) Foreign bodies.
4. Organic intestinal disorders:
  - (a) Neoplastic:
    1. Polyposis.
    2. Carcinoma.
    3. Other tumors.
  - (b) Non-neoplastic:
    1. Ulcerative colitis:
      - (a) Streptococcic.
      - (b) Tuberculous.
      - (c) Parasitic.
      - (d) Infectious diarrhea of undetermined etiology.
    2. Infectious dysentery:
      - (a) Bacillary dysentery.
      - (b) Typhoid fever.
    3. Granulomatous lesions:
      - (a) Tuberculomas.
      - (b) Amebic granulomas.
      - (c) Infectious granulomas (nonspecific).
    4. Regional enteritis, colitis, and enterocolitis.
    5. Deficiency diseases:
      - (a) Pellagra.
      - (b) Sprue

fact remains that a thorough systemic examination of the intestine must be made in order to determine the cause of any diarrhea. The cause of diarrhea should never be considered either unknown or functional until disease of the intestine has been excluded.

The most important diagnostic method in cases of diarrhea is the taking of detailed histories. However, to rely on the history alone will result in many regrettable errors of omission.

Many physicians will recall cases of irritable colon in which treatment for colitis was employed for months or, what is more serious, they may recall cases of carcinoma in which the mistaken diagnosis of colitis was adhered to until chance of cure had faded. Therefore, while a history is an indispensable and most important guide to the diagnosis, no other group of conditions which produces similar symptoms lends itself so well to further routine study as do conditions associated with diarrhea. A well-regulated set of objective investigations will lead to the correct diagnosis in nearly all cases of diarrhea.

### SYMPTOMS

Although some authors make an attempt to differentiate stools of so-called dysentery and diarrhea, for practical purposes they may be considered under the same general heading. The distinction between dysentery and diarrhea is more apparent than real, and dysenteric stools may alternate with diarrheal stools in a single case. Of greatest value is the nature, type, and severity of the diarrhea in a given case. Whether a patient has twenty loose, watery stools, or three or four mucopurulent rectal discharges is of great diagnostic importance. The rectal discharge of bloody, purulent material without much, if any, solid material is suggestive of chronic ulcerative colitis. On the other hand, the stools of patients who are suffering from intestinal tuberculosis, amebiasis, bacillary dysentery, food poisoning and so forth are so variable that they only occasionally contain gross positive diagnostic evidence.

The presence of blood in the stool is always indicative of some type of organic disease. The manner in which blood is ejected from the rectum may offer suggestions of the nature of the lesion. If passed separately, just before, or surrounding the stool, it is more than likely the result of local anal disease. If intimately mixed with mushy stools or purulent discharges, it is the result of disease above the anus, probably in the rectum or above. The freshness of the blood is in direct ratio to the proximity of the disease to the distal segments of the large intestine. It is well to consider all rectal bleeding as attributable to carcinoma until proof to the contrary is available.

The presence or absence of mucus in the stool has no diagnostic significance. Mucus is the normal colonic secretion.

The quantity of pus in the stools or rectal discharges has great significance.

Patients who have diarrhea may or may not have pain. The pain may be of two principal types. One type, which is spoken of as tormen, consists of griping, colicky distress in the abdomen and is associated with lesions of the right half of the colon. The other type, which is known as tenesmus, occurs with painful, spasmodic contractions, is accompanied by a feeling of incomplete evacuation and straining, and is associated with lesions in the distal segments of the large intestine.

Emaciation, rapid loss of weight, and anemia are frequently associated with diarrhea.

#### GENERAL PHYSICAL EXAMINATION

General inspection of the patient is important. The facies is often suggestive of the type of disease. Pallor and anxiety occur with severe organic disease or, on the other hand, full robust features may be noted in cases of functional disorder. Examination of the thorax may elicit the findings of tuberculosis. The scaphoid abdomen may suggest tuberculosis or chronic ulcerative colitis. The cord-like feeling imparted by the colon, if on the left side, may be suggestive of chronic ulcerative colitis, or if on the right side, it may be suggestive of other inflammatory disease. Finally, the most important part of the physical examination is careful, digital examination of the rectum. The wall of the rectum in all functional disorders is soft and pliable, and the mucosa is smooth and velvety. The wall of the rectum in amebiasis and tuberculosis may also be soft and pliable but if lesions have involved the rectum, irregular depressions will be found in the mucosa. The wall of the rectum in chronic ulcerative colitis will be stiff, and thick; the lumen will be narrowed, and the mucosa will appear roughly granular. Polyps in the rectum are readily palpable and carcinoma imparts a characteristic feeling to the finger.

#### ORDER OF SPECIAL EXAMINATIONS

There is probably no other symptom-complex in which the order of special examinations is as important as it is in conditions associated with diarrhea.

**Examination of Stools and Rectal Discharges.**—Stools and rectal discharges should be examined first and repeatedly until the examiner is thoroughly satisfied about the presence of suspected bacteria and parasites. Gross inspection of the stools is important. In some stages of chronic ulcerative colitis the characteristic sanguinopurulent rectal discharges alone allow a diagnosis to be made. Microscopically, the large amount of pus is striking. Charcot-Leyden crystals are, almost without exception, abundant. Streptococcal forms of bacteria predominate.

A typical stool of bacillary dysentery contains a relatively small amount of pus, and a great deal of mucus. It is usually liquid; it even may be "ricewater-like" and may contain blood. Although this condition is relatively rare in the northern half of this continent, its presence should be considered in every case of severe dysentery. Then, too, a few men have described chronic ulcerative colitis as a phase of bacillary dysentery. Hence, one should constantly be on the alert for the presence of the latter condition. Microscopic examination of the feces of patients who have bacillary dysentery will reveal many large phagocytic cells, which may easily be confused with amebæ for these cells also may contain erythrocytes. Staining will readily distinguish these cells from amebæ. An important point regarding the cultures of stools of patients who have bacillary dysentery concerns the fact that the stools should be examined immediately after they have been passed. Colonel Craig said: "The patient should be removed from the bedpan in order to inoculate media, preferably at the bedside." The reason for this great haste in examining stools is the fact that it has been demonstrated that the organisms undergo autolysis on standing. Various types of *Shigella paradysenteriæ* (dysentery bacilli) have been demonstrated in the Northwest; among them many mention the types of Flexner, of His and Russell, and of Sonne. *Shigella dysenteriæ* has not been encountered in this part of the country.

Although typhoid fever probably should not be considered among disorders associated with diarrhea, it has been estimated that more or less severe diarrhea may occur at times with passage of blood in a third of the cases, during the first half of the illness. Hence, this disease should be kept in mind in a study

of any severe type of diarrhea. The *Eberthella typhosa* can be isolated from the stool or urine in about half of the cases during the first two weeks of the illness, and even more frequently during the third week. Inasmuch as there is nothing characteristic about the stools in the cases of typhoid fever in which diarrhea is present, the importance of suspecting this disease in cases of diarrhea becomes apparent.

Another disease in which the study of stools is the most important diagnostic procedure is amebic dysentery. In acute amebic dysentery, the typical stool will contain dark brown shreds of mucus, and the whole stool, which is usually small in volume, will be a dark brick-red color. Flecks of bloody mucus may be mixed with the stool. These flecks of mucus often contain large numbers of amebæ. It is best to examine liquid stools in searching for amebæ. The finding of the *Endamœba histolytica* in the stools of patients who have diarrhea or dysentery is significant, and although the host may be only a carrier of this organism, its presence goes far in establishing a diagnosis.

In intestinal tuberculosis the gross appearance of the stools gives but little help. Gross blood rarely is present. The stools may be liquid or soft, and even may be formed. One should be suspicious of this lesion in a case of colonic ulceration in which the presence of pulmonary tuberculosis has been demonstrated.

There is another type of diarrhea which occurs in association with food poisoning. An intestinal disturbance often has been blamed on something the patient ate. Such a diagnosis has often been found competent, but more definite information is at present available and unless the condition promptly subsides, examination of the stools should be undertaken. The gastro-enteritis associated with food poisoning is apparently caused by various organisms, of which the staphylococci are the most prominent.

There is no peculiar characteristic about the stool of a patient who has polyposis, except that it will contain blood. The same can be said about the stool of a patient who has carcinoma of the colon.

**Proctoscopic Examination.**—The proctoscopic examination is the second most important test to determine the cause

of a diarrhea. It is well to wash out the rectum with warm enemas before performing the proctoscopic examination. Examination of the stools should be performed before the proctoscopic examination. Many organic lesions of the colon can be positively diagnosed by visualization through the proctoscope or sigmoidoscope. Thus, the pictures of uncomplicated chronic ulcerative colitis, tuberculosis, and amebiasis are characteristic. Proctoscopic examination of the rectums of patients who have polyps or carcinoma offers the added advantage of allowing removal of specimens. Frequently, the diagnosis of diverticulitis can be made through the proctoscope by visualization of the upper rectal sacculum and spasm. Proctoscopic examination is of great importance in functional colonic disorders, because it discloses the fact that the lining of the bowel is normal.

**Roentgenologic Examination.**—The roentgenologic examination should always be the final one of the series of examinations. The most important aid in a satisfactory roentgenologic examination is an empty colon. Consequently, the administration of some purgative, followed by intestinal irrigation, is essential. At the Clinic we follow a program something like the following one: The patient receives a dose of castor oil a day previous to the examination. No food is given for eighteen hours before the examination. On the morning of the examination, enemas are given until they return clear. The best results are obtained by retrograde filling of the colon by the barium enema, followed by evacuation of the colon and then by the injection of air under roentgenoscopic control. With the barium enema, gross filling defects will be detected and on the roentgenogram, which is made after evacuation, the mucosal pattern and any lesion disturbing it can be seen. Following the insufflation with air, small intrinsic lesions can be detected. Each one of the chronic organic intestinal lesions will present characteristic roentgenologic deformities in the colon. To detect lesions in the small intestine, it may be wise to observe the barium meal as it passes through the small intestine. If this becomes necessary, it should always follow the examination with the barium enema and should not precede it.

**Other Procedures.**—Other procedures may be advisable in the study of any given case of diarrhea. These may include

of any severe type of diarrhea. The *Eberthella typhosa* can be isolated from the stool or urine in about half of the cases during the first two weeks of the illness, and even more frequently during the third week. Inasmuch as there is nothing characteristic about the stools in the cases of typhoid fever in which diarrhea is present, the importance of suspecting this disease in cases of diarrhea becomes apparent.

Another disease in which the study of stools is the most important diagnostic procedure is amebic dysentery. In acute amebic dysentery, the typical stool will contain dark brown shreds of mucus, and the whole stool, which is usually small in volume, will be a dark brick-red color. Flecks of bloody mucus may be mixed with the stool. These flecks of mucus often contain large numbers of amebæ. It is best to examine liquid stools in searching for amebæ. The finding of the *Endamœba histolytica* in the stools of patients who have diarrhea or dysentery is significant, and although the host may be only a carrier of this organism, its presence goes far in establishing a diagnosis.

In intestinal tuberculosis the gross appearance of the stools gives but little help. Gross blood rarely is present. The stools may be liquid or soft, and even may be formed. One should be suspicious of this lesion in a case of colonic ulceration in which the presence of pulmonary tuberculosis has been demonstrated.

There is another type of diarrhea which occurs in association with food poisoning. An intestinal disturbance often has been blamed on something the patient ate. Such a diagnosis has often been found competent, but more definite information is at present available and unless the condition promptly subsides, examination of the stools should be undertaken. The gastro-enteritis associated with food poisoning is apparently caused by various organisms, of which the staphylococci are the most prominent.

There is no peculiar characteristic about the stool of a patient who has polyposis, except that it will contain blood. The same can be said about the stool of a patient who has carcinoma of the colon.

**Proctoscopic Examination.**—The proctoscopic examination is the second most important test to determine the cause

of a diarrhea. It is well to wash out the rectum with warm enemas before performing the proctoscopic examination. Examination of the stools should be performed before the proctoscopic examination. Many organic lesions of the colon can be positively diagnosed by visualization through the proctoscope or sigmoidoscope. Thus, the pictures of uncomplicated chronic ulcerative colitis, tuberculosis, and amebiasis are characteristic. Proctoscopic examination of the rectums of patients who have polyps or carcinoma offers the added advantage of allowing removal of specimens. Frequently, the diagnosis of diverticulitis can be made through the proctoscope by visualization of the upper rectal sacculation and spasm. Proctoscopic examination is of great importance in functional colonic disorders, because it discloses the fact that the lining of the bowel is normal.

**Roentgenologic Examination.**—The roentgenologic examination should always be the final one of the series of examinations. The most important aid in a satisfactory roentgenologic examination is an empty colon. Consequently, the administration of some purgative, followed by intestinal irrigation, is essential. At the Clinic we follow a program something like the following one: The patient receives a dose of castor oil a day previous to the examination. No food is given for eighteen hours before the examination. On the morning of the examination, enemas are given until they return clear. The best results are obtained by retrograde filling of the colon by the barium enema, followed by evacuation of the colon and then by the injection of air under roentgenoscopic control. With the barium enema, gross filling defects will be detected and on the roentgenogram, which is made after evacuation, the mucosal pattern and any lesion disturbing it can be seen. Following the insufflation with air, small intrinsic lesions can be detected. Each one of the chronic organic intestinal lesions will present characteristic roentgenologic deformities in the colon. To detect lesions in the small intestine, it may be wise to observe the barium meal as it passes through the small intestine. If this becomes necessary, it should always follow the examination with the barium enema and should not precede it.

**Other Procedures.**—Other procedures may be advisable in the study of any given case of diarrhea. These may include

the analysis of the gastric contents, investigation of allergy, determination of the basal metabolic rate, and tests for elimination. Invaluable information will be obtained by blood cultures in typhoid fever or by agglutination tests, such as the Widal test in typhoid fever or similar tests in bacillary dysentery. Important information at times can be gained by the study of blood smears. In the aggregate, however, these tests will give information in a relatively small number of cases.

#### TREATMENT

**Systemic Disturbances.**—When it has been definitely established that a diarrhea is the result of a disturbance of this type, treatment may often be very difficult. The most important factor in a well-regulated program of management in these cases has to do with convincing the patient that the diarrhea is of this nature. It may not be easy to establish in the mind of an individual that his nervous irritability is causing a diarrhea. For this reason, the objective tests which have been described become an important part of the treatment. When the nature of the systemic disturbance has once been established, the treatment of the diarrhea itself becomes a secondary problem. The patient may have to avoid those things which upset his nervous system. He may have to avoid certain foods which are followed by intestinal disturbances. Of course, when diarrhea is the result of such things as food poisoning and trichinosis, the specific treatment of these is in order. When it is caused by exophthalmic goiter the adequate treatment of the hyperthyroid state will result in the control of the diarrhea. In my experience, diarrhea only occurs in the late stages of uremia, when treatment of the uremia state may not be possible. In any event, however, the treatment should be directed to the renal condition rather than to the intestine. The same things may be said about the control of the functional gastrointestinal disturbances. The so-called irritable colon, or unstable colon, which also has been described by some writers as "mucous colitis," is a condition in which the intestine plays only a small rôle in the production of the diarrhea. The colon is only one of the organs whose function is deranged. While relief of the diarrhea may be advisable, the major part of the treatment should consist of the control of the general bodily

disturbance. Frequently, frank talks with the patient, in which every effort is made to dispel acquired fears and to replace them by exact information as to the nature of the difficulty, are important. It must be explained that sensitiveness of the colon is a characteristic part of that individual. Analysis of the patient's emotional and mental state becomes necessary. However, even when complete understanding and agreement between patient and physician have been established, the treatment is not ended. The patient must then be taught how to overcome and to live with a disability which, although not serious, is exceedingly troublesome. A detailed regimen should be outlined; this should include diet, physiotherapy, administration of drugs, and many other details from which the patient should not be allowed to deviate. No fixed regimen is possible for all of these patients. The program must be individual and will entail patience by the patient and physician alike.

**Organic Intestinal Disorders.**—The treatment of each of these conditions is essentially individual. The treatment for neoplastic disease has been well established and can be summed up by saying that it is essentially surgical and radiologic. The important consideration from the clinician's standpoint is accurate diagnosis.

**Ulcerative Colitis.**—In cases of ulcerative colitis the treatment for each type of this disease has been well established. In the condition known as chronic ulcerative colitis of the streptococcic type, the treatment is chiefly medical. The present management includes the following details: (1) rest and restful recreation, (2) a careful dietary program, (3) administration of serums and vaccine, (4) removal of foci of infection, (5) transfusion of blood, (6) supportive measures, (7) careful nursing, (8) physiotherapy, including hydrotherapy and occupation therapy, (9) administration of drugs, and (10) local treatments.

Chronic ulcerative colitis should be looked on much as is tuberculosis, and a well-regulated, graduated program of rest, which at first consists of rest in bed, then graded activity, and finally mild physical recreation, is in order.

Many patients who have had this disease have, in the course of time, omitted one food and then another from their diet so that ultimately their diet has become very limited. It is well

then to return them by easy stages to a generous, high-caloric, high-protein type of diet, beginning with easily assimilated, palatable, nonirritating foods and increasing the diet day by day as rapidly as their condition will tolerate. Not infrequently, solutions of dextrose administered intravenously or the subcutaneous administration of a physiologic solution of sodium chloride are indicated to restore an adequate fluid balance.

The serum prepared by immunizing horses against the diplostreptococcus of colitis may be administered intramuscularly or it may be administered intravenously in cases in which the condition is severe. Results with the use of this serum are most gratifying. The anticolon bacillus serum recently prepared by Schwartzman bids fair to have value. The reactions from anti-dysentery bacillus serum are frequently so severe that its use is indicated only in cases in which the condition is resistant to treatment. Its value as anything more than a nonspecific foreign substance is problematical. Vaccines prepared from the diplostreptococcus which has been isolated from the rectal ulcers should be administered subcutaneously in cases in which the infection is less severe or when active and severe symptoms have subsided.

Distant foci of infection, particularly about the mouth, such as infected tonsils and abscessed teeth, should be removed.

Blood transfusions are of value in two phases of the disease: (1) when the individual has had a long siege of fever and sepsis, and (2) when he is anemic. A series of transfusions of small amounts of blood, that is, about 250 c.c. each, given every four or five days, for four or five weeks, have much greater value than one or two transfusions of larger amounts.

Osler has aptly said: "Disease above the diaphragm makes for optimism and that below the diaphragm for pessimism." Hence, in this disease, any measures which will produce physical stimulation and divert the patient's attention from his condition are in order. For this reason, mild forms of occupational therapy are of great value.

Many drugs have been advocated in the treatment of chronic ulcerative colitis. No single one has helped more than a few individuals. Sedatives, particularly codeine and other forms of opium, are decidedly indicated in severe forms of

the disease. Tincture of iodine, given by mouth, is of value in selected cases. Arsenic, in the form of stovarsol, treparsol (the methenamine derivative of meta-amino-para-oxyphenyl-arsenic acid), or carbarstone, is dangerous when used in the treatment of chronic ulcerative colitis. It frequently has seemed to be the basis of severe exacerbations. Its only indication is as a tonic and it should be administered in very small amounts after the patient has ceased passing blood. A warning should also be expressed about the use of mercury in such forms as mercurochrome.

Local treatments are indicated only when there is much anal discomfort, as from fissures and fistulas, or when the lesions are confined to the most distal segments of the large intestine. Chronic ulcerative colitis is not a disease of the mucosa but of the intestinal wall, and hence colonic irrigations not only fall entirely short of the purpose for which they are intended but often cause irreparable irritation.

From these remarks, it becomes obvious that a well-regulated program of activities is necessary for adequate treatment of patients who have chronic ulcerative colitis.

**Parasitic Disease.**—Although, in various parts of the globe, many parasites inhabit the human intestine, for practical purposes a consideration of the treatment of amebiasis will suffice. Chemotherapy plays a very important rôle in the treatment of amebic dysentery. The purpose of therapy in these cases is twofold: (1) to eradicate the parasites in the walls of the intestine and in other distant foci, and (2) to promote healing of the lesions they have produced.

The following combinations of drugs have been found to produce these results in a very satisfactory manner. In the average case, emetine hydrochloride  $\frac{2}{3}$  grain (0.043 gm.) is administered hypodermically, twice a day, until 4 grains (0.24 gm.) have been given. In cases in which the disease is more acute 1 grain (0.065 gm.) of emetin hydrochloride, is administered twice a day, until a total of 6 grains (0.4 gm.) have been given. At the same time, tablets of treparsol, each of which contains 0.25 gm. of the drug, are administered. One tablet is chewed before each of twelve successive meals (three tablets a day), the course of treatment taking four days. A rest for a week follows, and the same course of treatment is

repeated. Two courses of treatment with emetine are usually sufficient, and it is seldom safe to give more. Three courses of treatment with treparsol are usually required. Between the second and third courses of treatment with treparsol, and after the third course, one of the compounds of iodine, such as chiniofon may be given. This is prescribed in the form of tablets which contain 0.25 gm. of the drug.

Diet should be generous but bland; it should be graded more bland or less bland, according to the severity of the disease.

After completion of the course of treatment, the stools should be examined by a competent parasitologist, and the examination should be repeated again in several months.

**Tuberculosis of the Intestine.**—The common type of intestinal tuberculosis secondary to disease of the lungs resembles amebiasis in its involvement of the intestine. No specific treatment for it is as yet available, hence the differential diagnosis of these two conditions is of utmost importance. Rest in bed and heliotherapy constitute the keynote of treatment. The object must be to take as much of the burden off the inflamed and handicapped bowel as is possible. The diet should be somewhat similar to that used in chronic ulcerative colitis; it should be smooth, relatively low in residue and high in calories. Attempts at specific treatment have included the injection of oxygen into the peritoneal cavity, roentgen therapy over the abdomen, injection of oxygen into the abdomen, and even opening and closing the abdomen surgically. Among the drugs which have found favor in the treatment of this condition are calcium, arsenic, and mercury. Many other drugs have been employed but the important thing to remember is that intestinal rest is of paramount importance. The prognosis of tuberculous enterocolitis is unfavorable and the condition usually is a terminal process.

**Infectious Dysentery.**—The management of any patient who has acute dysentery should be the same as the management of a patient who has one of the transmissible forms of dysentery, such as typhoid fever or bacillary dysentery. Precautions that accompany isolation should be applied. The diagnosis will usually be settled by blood cultures or agglutination tests, such as the Widal test for typhoid fever or similar tests for bacillary

dysentery. Once the diagnosis has been settled, the usual supportive measures described for severe chronic ulcerative colitis are in order. Of utmost importance in the management of the patients is their nursing care. Various types of diets have been suggested; those high in carbohydrates and low in residue have found greatest favor. Specific treatment, such as administration of a serum or a bacteriophage and the later administration of vaccines, should be employed in these cases.

**Granulomatous Lesions.**—At this time the accepted treatment of tuberculomas and infectious granulomas (nonspecific) is surgical. Some form of short-circuiting operation, usually followed by resection, is in order. Here again, however, it is of utmost importance to distinguish these lesions from the so-called amebic granulomas for in the latter condition specific anti-amebic treatment will usually suffice unless paracolonial infiltration has become so great that obstructive features predominate.

**Regional Enteritis.**—This condition which has been considered an entity only in recent years, is an infectious disorder of localized segments of the intestine. The best treatment is still debatable but most men with considerable experience in handling the condition are advising surgical excision of the affected segment or segments, as "skip areas" often are present.

**Deficiency Diseases.**—More time and space than are available for this entire paper could be adequately devoted to a consideration of these diseases. For practical purposes, pellagra and sprue are probably the principal ones requiring consideration. It is important to determine, if possible, just what is lacking in any given case of deficiency and then treat the patient by supplying the food, mineral or other substance which is the cause of the deficiency. In a case of active pellagra, a high calorie and high vitamin diet is probably the most important single measure of safety. Supplying all the necessary food elements, and at times supplying more than adequate quantities, may be enough to control the pellagra. At the onset an excess of vitamin B should be given by using B concentrates. In a case of sprue, the factor of anemia is frequently one which must be dealt with very drastically, hence the administration of many of the drugs used in the treatment of anemia may be indicated. Liver extract, preferably administered hypoder-

mically, is of value in the treatment of sprue. Dilute hydrochloric acid, administered by mouth, may be advisable as substitution therapy. A diet rich in carbohydrates, high in proteins and relatively low in fats has been most efficacious. Frequently even carbohydrates are poorly tolerated at the onset and must be added slowly. Deficiencies may be secondary to any other bodily state that may be associated with diarrhea. These are usually best managed by control of the basic pathologic changes.

#### SUMMARY

I have attempted to offer a few practical suggestions for the control of some of the common diarrheas. A perusal of this paper will promptly bring to mind other conditions associated with diarrhea. Space will not allow individual consideration of all these conditions. Most of the other diarrheas, at least those found in the North Temperate Zone will represent symptoms of other bodily disturbances which at times are distinct from the intestine. Their management is usually individual and symptomatic.

## "SPASTIC COLITIS"; FUNCTIONAL DISORDERS OF THE COLON AFFECTING YOUNG AND MIDDLE-AGED INDIVIDUALS

E. G. WAKEFIELD

---

THE functional disorders of the colon, often termed "spastic colitis," "colitis," "constipation," or "irritable colon," are manifested by irregularity of evacuations and by apparent alternation in the absorptive and secretory functions of the colon. These terms are usually applied to conditions which are considered as separate clinical syndromes. It is our opinion at the Clinic that this is not the best conception of functional disorders of the colon. These separate syndromes are phases of the same clinical disorder. Since this is true, the clinical symptoms will be described first in order to define the condition clearly.

### SYMPTOMS AND PHYSICAL SIGNS

The irregularity of the evacuations may vary from one bowel movement a week to ten or twelve or more in twenty-four hours. When there are infrequent evacuations, the feces often are like pellets and are tangled in masses of slime. Between irregular defecations there may be passages of slime or mucus, which may be formed or cast, the so-called "mucous casts." Periods of increased evacuations are characterized by an apparent increase in the volume of watery feces which may also contain slime or mucus. In any one case there may be periods in which there are all gradations between the extreme degrees of constipation and diarrhea. Some patients constantly have varying degrees of "loose stools" while others always are extremely constipated. Characteristically, in cases in which the stools are loose, the patients have their bowel movements after meals, especially after breakfast. It is very rare that

the nocturnal sleep is disturbed once sound sleep has been obtained. Abdominal discomforts to the degree of real pain may be present. The pain is usually low in the abdomen and most frequently along the course of the colon and on the left side; however, no part of the abdomen is exempt. The pain may be associated with bowel movements. The severity of these disorders of the colon may be measured by observing the frequency and degree of the symptoms and the ease with which the colon may be provoked to change its habits so widely. A patient who has had a long-standing disorder of the colon which has not been associated with the passage of feces containing blood, with remission of symptoms, and with loss of weight will usually be found to have a functional disorder of the colon. The disorder which has been termed "irritable colon" or "spastic colitis" is often characterized by paroxysmal attacks of abdominal pain which are associated with fatigue that follows either emotional disturbances or physical strain.

The clinical history of a functional disorder of the colon may reveal the presence of every known symptom which can arise from organic disease of the colon. In eliciting the history in a case in which the symptoms are referable to the intestines, there are certain points which should be clearly elucidated. Organic diseases of the colon, as a rule, are characterized by fever, loss of weight, blood in the feces, and symptoms which awake the patient after he has gone to sleep at night. These symptoms are usually absent in functional disorders. Loss of weight, if present in cases of functional disorder of the colon, can usually be accounted for by sitophobia, or are the result of a diet which has been prescribed by a "diet specialist." The history of a change in bowel habits has been considered almost an infallible sign of organic disease. This change may vary from constipation to diarrhea or there may be alternating constipation and diarrhea. A change in bowel habits would also include the opinion of the patient that the action of the intestine was not right or had changed in some indescribable way. If one could accurately elucidate this point in the history, its value in the differential diagnosis of organic disease would be established; however, in reality, the so-called alternating diarrhea and constipation can usually be definitely attributed to the taking of laxatives. If the use of laxatives could be avoided

in organic disorders of the intestine, the trend would be definitely toward either a constipation or a diarrhea. In other words, the colon which is organically diseased tends to maintain a stability of function, whereas, in the presence of a functional disorder the colon tends to lose this stability and, as has been stated, may be easily provoked to change its habits widely. The stability of the action of the colon is best illustrated by pointing out that at least two-thirds of those who have carcinoma of the colon are not disturbed by any degree of irregularity of intestinal action, and they do not seek relief until there is abdominal pain or discomfort, sudden onset of obstruction, or rectal bleeding which causes them to become alarmed about the extent of the loss of blood and the weakness.

The general physical examination of a patient who has a functional disorder of the colon does not reveal anything that is characteristic. Many normal persons have a palpable cecum, a palpable ascending colon, or a palpable sigmoid flexure. The loss of weight, hyperactive reflexes and subjective abdominal tenderness are of no real diagnostic value. If the abdomen is tender, similar tenderness often can be elicited by pressure over various parts of the body, especially over the distal portions of the tibiae. There is a general increased susceptibility to pain. There may be a pathologic tendency toward fabrication, evasiveness, arrogance, irritability and fixed ideas concerning the illness but this is not peculiar to disease of the colon. Direct visualization of the rectum, rectosigmoid and sigmoid flexure with the sigmoidoscope will reveal a normal mucous membrane. Roentgenographic examination of the colon in these disorders might be of specific diagnostic value if a properly controlled series of normal persons were available for comparison. In the roentgenologic study of such a controlled series of normal persons, due consideration would have to be given to the limits of the varying responses of the colon to the preparation for the examination and to the effects of the presence of the mass and volume of the opaque material and feces in the intestine. At the present time the great value of roentgenologic examination of the colon in cases of functional disorders of the colon is the ruling out of deforming lesions. The roentgenologist is familiar with the fact that roentgenologic examination may reveal great coils of the intestines which are kinked and

tethered by adhesions and knows that acute bends of the colon may be present without producing clinical symptoms. Furthermore, the roentgenologist is fully aware of the fact that whether the colon is on the right or left side, or whether its flexures are under the costal margins or in the pelvis, its functions may still be normally performed.

### ETIOLOGY

The etiologic theories of functional disorders of the colon comprise an interesting chapter of medical history. These disorders have long been the bane of many human lives. It is fairly safe to say that the human race has suffered from these disorders since the dawn of civilization. The ancient Egyptians purged themselves three days in succession each month, thus seeking to preserve health with emetics and clysters, for they supposed that all diseases were the results of accumulation of refuse in the intestines. Europeans during the Middle Ages resorted to the use of the horoscope to determine the proper time for emesis and purgation, while the American Indians and ancient Babylonians had fixed periods for ritual emesis and catharsis. It has been observed that the feces contained in the rectum of a mummy found under a bluff in the plateau region of the Ozark Mountains was in the form of pellets, in other words, a constipated stool. This mummy lived 2,000 or more years ago. It was not until the eighteenth century, when John Howship recorded under the heading of "Practical remarks on the discrimination and successful treatment of spasmodic stricture in the colon considered as an occasional cause of habitual confinement of the bowels," that there was any evidence of a clearly stated conception of the etiology of functional disorders of the intestines. Howship considered these illnesses to be the result of a deficient freedom of relaxation in some part of the intestinal canal. However, his reports contained at least one case which was most likely an example of an organic disease. In this case the condition was probably an intussusception of the small intestine. This report of Howship was mainly valuable, as has been stated, for the conception that it contained, a conception which seems to have been quickly lost or completely forgotten because medical writers continued to be enamoured by the "beneficial effects of purg-

ing." About the only evidence that a failure of relaxation of the intestine was a part of the disease is indicated in the term "spastic colitis," which is probably a hybrid linking the conception of Howship with the more modern science of bacteriology.

On the discovery that the human colon was a culture tube for very large numbers of bacteria, many ill-advised conclusions were formulated, which suggested the theory that all the diseases of the colon and the lower part of the intestine were caused by microorganisms, and the term "colitis" consequently was applied to any obscure disorder of the colon. This illegitimate use of the term had, and has maintained, a popular appeal. So popular is the term "colitis" that no other one will satisfy many patients who have a functional disorder of the colon. Recently, however, "colitis" has lost some of its appeal. The "allergists" have opened a show on the same lot, and by making skin tests "prove" to the satisfaction of the unfortunate patient that his discomfort is attributable to being sensitive to protein or other foods. I know of one patient who was convinced that she was sensitive to sixty-one foods. The theory of alleged allergy to food is most gratifying and convincing to those patients who have, as a part of their functional colonic disorder, sitophobia. It gives them an objective reason to insist on odd dietary regimens. At the present time, one cannot avoid the impression that infection, allergy to food, and the like can be important etiologic factors in only a small percentage of the total number of functional disorders of the colon.

The etiology of functional disorders of the colon is a mirror image of the hereditary taints, congenital endowments, physical and mental attainments, and abuses since birth. That is, the symptoms may be referable to the colon but the etiology is extrinsic. The various functional disorders of the intestine, which have been described under various headings, such as "spastic colitis," "nervous diarrhea," "mucous colitis" and many other terms, are phases of one and the same disorder. The etiology of this disorder may vary widely. Some of the etiologic factors are systemic diseases with colonic symptoms, environment, tear of disease, laxatives, allergy, irregular habits, hereditary, and congenital malformations. In all cases of functional disorder of the colon there are varying degrees of fatigue, fear,

anxiety and a general failure of relaxation, which are combined with one or more of the foregoing factors. The limits of the presenting complaints are the limits of the human imagination, but, in the opinion of the patient, the bowels always occupy a paramount position in the production of physical discomfort. Systemic disease is the paramount issue to be made in all cases of suspected functional disorders of the colon. The symptoms of a functional disorder may be impossible to distinguish from those that would be present if there was some underlying organic disease. Noteworthy of the diseases which in their early stages or during their progress may be confused with functional disorders are pellagra, mild regional ileitis, and certain forms of sprue. Pernicious anemia associated with achlorhydria may also be confusing. Chronic poisoning with heavy metals, such as lead, which produce obstinate constipation and intestinal colics, combined with the abuse of the bowel by the use of strong purgatives and enemas may produce symptoms which will require careful and appropriate studies in order to make a differential diagnosis. During the course of many diseases, such as exophthalmic goiter and Addison's disease, the functions of the intestine may be deranged. Fevers, infectious diseases, septicemia, malnutrition from any cause, pelvic and abdominal tumors, deranged functions of the pancreas, liver and kidneys are at times accompanied by colonic symptoms to the degree that the underlying disease is masked.

**Environment.**—The surrounding conditions, influences or forces which hem in and daily influence the thoughts, actions and the physical activity of any person may be disagreeable enough to be inciting factors in the production of functional disorders. An environment of poverty, if the patient is accustomed to it, is conducive to the development of organic digestive disorders; whereas, an environment of luxury, especially if newly acquired, such as by the marriage of a poverty-stricken young woman to an elderly wealthy bachelor, is ideal for the development of functional disorders of the colon. One might argue that the example just cited was on the basis of sex. In certain instances this may be true, but not always. Family disagreements, social aspirations, ambitions by mothers for attaining the "greatest opportunity" for their children are common environmental factors of importance. Examples of an

environment in which sex may play an important rôle are seen among young women who have had college romances which have terminated unhappily. After the glamour of college life is over they are forced to retreat to a village or rural community to teach school where there are no "eligible" young men. The sex instinct under environmental influences is of the greatest etiologic importance in the marriage of a frigid, fearful woman to a robust philandering husband. A changing environment is of the greatest importance, especially when the changes create surroundings which are incompatible with the physical and mental qualifications of the patient.

**Fear of Disease.**—Fear is an important etiologic factor in the production of functional colonic disorders. However, here the consideration will be limited to the fear of disease. The fear of disease has found a tangible ally through advertisements of remedies to prevent auto-intoxication and colitis. These advertisements may be very suggestive in their implications as to the prophylactic and hygienic qualifications of the remedies in the treatment of these spurious conditions. The fears of the patients should be treated with the greatest of caution and sympathy by the physician. If the physician assumes a jocular attitude toward these patients, they will be driven into the hands of a sympathetic individual who will employ ill-advised and infamous treatments which will result in the subsequent development of unmanageable disorders of the colon. Nothing should be spared in the way of sympathy and examinations to convince these patients they do not have organic disease. In families in which one or more members have suffered from disseminated polyposis or carcinoma of the colon or rectum, or from chronic ulcerative colitis, a fear of these maladies is a natural human tendency. This fear is often precipitated by the presence of mucus in the feces. Mucus is a normal but variable secretion of the colon and not a sign of disease. This fact is worthy of great stress to those who fear its presence in their feces.

The patients who suffer from functional disorders which result from the fear of disease of the colon or elsewhere in the body may be classified in two groups. The first group comprises those who are intelligent and who have a good sound basis for their fear, such as an unexplained diarrhea following

a recent attack of pulmonary tuberculosis or time spent in a tropical climate. The second group includes patients whose judgment is fallacious. Their conception is that they have a disorder of the bowels; their complaints and their "case" is different from any the physician has ever seen. They are worthless to themselves, miserable, arrogant, evasive and difficult, if not impossible to treat successfully. The patients in the first group, however, are both amenable and amendable.

**Laxatives.**—The use of laxatives is as old as the human race itself. It seems to be almost instinctive for carnivorous or near carnivorous animals, such as man, to empty the stomach and intestines when they do not feel well, that is, the dog may invoke vomiting by eating grass. These facts make it easy to understand that the human race as a whole is easy prey to the alleged beneficial effects of "liver pills." When the colon has been emptied with a laxative, it fills up with liquid feces and gas. If there is any tendency to irritability, the presence of the gas and fluid will produce discomfort. This discomfort will be greatly enhanced by the repeated emptying and the resulting stimulation of the bowel by the laxative. It is doubtful, however, that the repeated use of laxatives by normal individuals would produce anything more than a mild functional disorder of the colon which would recover as soon as purgation was discontinued. In the habitual use of purgatives the colon is punished because of erroneous ideas of its proper function.

**Allergy to Food.**—In recent years much attention has been directed toward the possibility that many persons who have an irritable colon might in reality be suffering from an allergy to food. In so far as the total number of these patients is concerned, a relatively small percentage of them will respond favorably to the so-called elimination diets or will give positive dermal or intradermal tests with food extracts. There are very definite rules which should be kept in mind when it is thought necessary to make a survey of foods for possible detection of allergic phenomena. The patient should have: (1) symptoms which can be explained by spasm of smooth muscle, (2) other manifestations of allergy, (3) positive family history for allergy, (4) positive skin tests, and (5) eosinophilia. If a patient does not present these findings one is left to the un-

certainities of "elimination diets." The interpretation of the results obtained when an elimination diet is employed is wholly dependent on the patient's interpretation of the effects of foods. The physician's opinion may be unscientific if a possible easy chance to please the patient arises. The results, therefore, are influenced by two uncontrollable errors: (1) the patient's interpretation that foods are harmful, and (2) the physician's estimation of the improvement. Certainly, such evidence is not good in a disease in which sitophobia may be a prominent symptom.

**Irregular Habits.**—Irregular habits, especially bowel habits, are a most important etiologic factor in the production of a functional disorder of the colon in cases in which there is a tendency toward constipation. A certain degree of relaxation during work, sleep, and periods of full relaxation such as obtained while on a good vacation are necessary as well as a normal bowel movement and the development of the habit of a regular time for visits to the toilet. Irregularity prevents relaxation and annuls sensations. A sizeable percentage of functional disorders of the colon would cease to exist if regular habits of eating, sleeping, going to the toilet, and physical exercise were instituted. When there is an increased number of bowel movements during the day, regular habits for meals without extreme temperatures of foods and beverages may be most beneficial. Ingestion of hot or ice-cold materials increases the so-called gastrocolic reflex. Loose bowel movements are therefore to be expected if such indiscretions are practiced. In cases in which the gastrocolic reflex phenomena are extreme, ingestion of foods at body temperature on a fasting stomach will incite repeated bowel movements. An indeterminate number of habits practiced by these patients are so deeply seated through environment that the patients are not aware that what they do is wrong. Such habits cannot or may not be elicited in taking the clinical history.

**Heredity.**—The immeasurable composition of the patient is of the greatest importance, especially in cases of functional disorders of any kind. The physical stature of the parents greatly influences that of the offspring. The same is true of mental habits, conduct, hours of sleep, foods and drinks. Heredity, environment and habits are so intimately associated

and interwoven in the same individual that analysis by the average physician is impossible. If such an analysis is successfully made it will not change hereditary equipment. A painful functional disorder of the colon is rarely seen in the sturdy, muscular blonde. The tall, scant brunette with a "stylish figure" is the characteristic build to have a "spastic colitis" or "visceroptosis." Heredity plays an important rôle in all the foregoing etiologic considerations. It is regrettable, however, that the biologic or genetic data are insufficient to permit interpretation of the suspected hereditary factors in this disease. The congenital endowments of a person refer to certain mental and physical traits or peculiarities which existed at the time of birth. At birth one either possesses the type of nervous system of the stoic person or that of the "high strung," "nervous," irritable person. To these congenital attributes may be added the hereditary factors, which may be either beneficial or harmful, and the influences of environment, which also may be similarly interpreted. The hereditary and environmental factors may influence but not change the fundamental congenital endowments; that is, the nervous system which will manifest its control over the body by the production of a functional disorder of the colon is present at birth. One cannot avoid the impression that proper environment and hygiene prevent the physician from seeing many individuals who have the congenital endowments for such a disorder, and that unfortunate environmental influences bring many nearly normal persons to him. A person who has proper congenital endowments cannot have a functional disorder under any circumstances.

The congenital physical endowments are of the greatest importance in a negative way. The well-formed baby who has a gastro-intestinal tract that functions properly at the time of birth does not have any congenital factors of a physical nature that will predispose it to a functional disorder of the colon. That is, the physical structure of the colon does not play any rôle in these disorders. There may be congenital malformations of the colon, which are of two types. If the malformation is of sufficient degree it will prevent function. Congenital malformations such as dolichocolon, redundant sigmoid flexure and visceroptosis are of no etiologic importance.

### TREATMENT

The treatment of functional disorders of the colon, since the etiology is mainly extrinsic to the alimentary canal, must be directed toward the source of the disorder. Treatment is individualistic and must be outlined for each case. These patients insist on consulting the most successful physicians in the community. Such a physician often does not have time to spend in taking a long history and carefully pointing out the insignificance of their symptoms. These patients should never be told that they are only "nervous." Such a statement has no therapeutic value, and may serve to make the patient feel that the physician lacks interest. If possible, one should be sure that all fear of organic disease is removed. A thorough search for organic disease is reassuring to both the patient and the physician. It creates mutual confidence. The phenomena of pain are best explained on the basis of fatigue and increased sensitivity and susceptibility of the nervous system, which are produced by the failure to relax. The presence of mucus in the feces is not the result of infection in the bowel, but is evidence of deranged secretory function of the colon as a result of increased sensitivity and irritability.

The inspection of the feces is instinctive in man. This is an instinct of error when it is done with an idea of appraisal of digestive function. In reality, about 80 per cent of the mass of the feces represents dejecta from the alimentary tract and only 20 per cent represents the residue of undigested food. This residue consists of foods which are not digestible by the human alimentary system.

The greatest aid in treatment is an orderly consideration of the etiologic factors. The conception that these disorders arise in the colon and can be corrected by special dietary regimens designed to "harmonize" with any evolutionary anatomic or physiologic qualities of the human colon is erroneous. If a diet, no matter how complicated, would relieve the symptoms of this disorder, treatment would be simple and successful. The practical point here is to realize that a sitophobia, at least for some foods, is often present. Under such circumstances it may be difficult to get these patients to take a normal and well-balanced diet. This brings one to the very interesting question as to what is the structure of the human colon and

what are its comparative anatomic structural qualifications which indicate possible potential influences diet might have on the functions. The ideal way to approach this problem would be through a study of the natural foods man has taken during the various stages in his long evolutionary trek. This ideal cannot be obtained. Primitive man ate a great variety of foods, but this is the end of our knowledge. However, mammals in general can be divided into three groups according to the main sources of their natural food supplies. Each of these groups possesses certain definite anatomic alimentary structures according to the main source of food eaten. The first group, the herbivora, which partakes of plants, has, as a rule, an enormous and complicated colon which plays an active part in digestion. A colon with a large volume is necessary for the digestion of cellulose, because this material has to be retained in the body long enough for the enzyme citase, which is in the plant cell, to change the cellulose to simpler compounds—the starches.

The second group consists of the carnivora. If the alimentary structure of the common house cat is contrasted with that of the herbivora, one is immediately impressed with the differences. The structure of the alimentary tube of the cat is simple in design. There are no sacculations, blind pouches or complicated intestinal coils. The simple thick-walled, muscular stomach and intestines, for the most part, are attached to the coiled and lengthened primitive mesentery. The colon, except the cecum, is short, muscular and devoid of sacculations.

The third group consists of the omnivora. With the foregoing very brief anatomic considerations in mind, it may be pointed out that man occupies a position, comparatively speaking, near the carnivora. The alimentary tube of man is simple except for the rudimentary sacculations of the colon. The colon of the herbivora possesses important digestive functions. The colon of the carnivora does not have any digestive function so far as organic digestion is concerned.

In the laboratories at the Clinic, Welch has demonstrated that the colon of man does not possess digestive functions. Its sole function is the absorption of salts and water. Thus, the colon of man, although of a greater capacity than that of the carnivora, like the colon of the latter, does not possess im-

portant digestive functions. There is every reason to be positive that a patient who has a functional disorder of the colon should not be given a diet which contains a large amount of cellulose. There would be a more sound reason to prescribe an all-meat diet. Practical experience teaches that a man may live and even retain his health with a diet of meat or of vegetables. Common sense and instincts teach that such is neither wise nor necessary.

Diets of the omnivora, which are planned to harmonize with the anatomic and physiologic functions of the colon in the prevention of "auto-intoxication" and various other spurious ills, are not in keeping with the known facts. Man has no structural alimentary equipment for the digestion of cellulose. The fact that one can eat "all bran muffins," the husk and debris from all sorts of grain and endure them, is an evolutionary and structural anatomic privilege. Because man is either a facultative carnivore or herbivore does not mean that these attributes should be abused unnecessarily when he is functionally ill. A more severe violation of natural laws than the prescribing or overindulgence in foods such as those with a high content of cellulose is not known. A comparable mistake would be to feed meat to a sick ox.

In those functional disorders characterized by constipation, some dietary adjunct should be resorted to, which will increase the volume of the feces. Such an increase in the volume may be obtained by a material such as agar, which is chemically and physically inactive. This material is indigestible the same as cellulose. However, agar forms a soft gelatinous bulk which consists largely of water, whereas, the cellulose in the food remains hard and may have local stimulating effects similar to a more drastic laxative.

Such general hygienic measures as regular hours, regular periods of relaxation after meals, daily walks, and outdoor sports are to be encouraged. Mild sedatives, such as elixir of phenobarbital, 1 drachm (4 c.c.), administered before meals and at bedtime, may be useful. Tincture of belladonna, if given in proper dosage, may be beneficial to those who have abdominal cramps.

In severe disorders associated with a great number of bowel movements daily, rest in a hospital may be required. Tincture

of opium, camphorated tincture of opium, and the tincture of iodine are at times indispensable drugs in the treatment of these disorders. Generally, the tincture of iodine, administered in doses of 10 minims (0.6 c.c.) in a full glass of water, is of genuine value. A soft diet should be given. Liberal amounts of fluids are required to replace the loss of water through the feces. Evident interest, patience, and optimism on the part of the physician, who most constantly plans the regimen is the most successful plan of treatment.

In the treatment of the various phases of these colonic disorders, the tact and ingenuity of the physician may be given the greatest test. If the physician is resourceful enough, only death of either the physician or the patient, from other causes, will end the battle. No one can hope to be resourceful enough to treat more than some of these patients successfully. However, those who are successfully managed should be a great source of joy and are worthy of reflection as a professional accomplishment.

#### SUMMARY

All the functional diseases of the colon are phases of the same disorder, which has an etiology extrinsic to the bowel. The severity of these disorders may be measured by the ease with which the colon may be provoked to change its habits so widely. Of the etiologic factors, fear, anxiety, fatigue, and a failure to relax are present in varying degrees in all cases. These constant causes are usually associated with such factors as fear of disease; hereditary taints, congenital attributes, allergy, and the use of laxatives. These etiologic factors are often difficult to elicit and their discovery requires time and considerable patience. The treatment is difficult; it consists of convincing the patient that further search of the mystic and unusual etiology serves only to deplete his health. A reasonable diet and regimen for improvement of the general health are the therapeutic agents par excellence. These measures will rehabilitate all those who are really desirous of as near a normal existence as is possible to obtain, but will not cure any of them. These patients have sustained irreparable damages; fatigue, fear, anxiety, and a failure to relax will always produce a relapse. This point should always be made clear to the patient.

The dietary management of these functional disorders consists of: (1) overcoming whatever sitophobia that may be present; (2) an adequate, well-balanced diet which includes minerals, vitamins, and an adequate number of calories, but which does not contain large quantities of cellulose. The cooking of starches renders them more digestible, which is desirable in cases in which the patients are undernourished and have diarrhea. In other words, a minimal amount of raw fruits and vegetables should be given.

The bulk of the feces is alimentary dejecta and not food residue. A soft bland residue, such as is obtained by the administration of agar, is desirable to increase the bulk of the feces in cases of constipation. There are a great number and variety of these materials on the market, which will furnish a soft nonirritating bulk to the feces. The selection of such a substance should be made with great care since laxatives frequently have been added.

## VITAMIN DEFICIENCY DISEASES: THEIR DIAGNOSIS AND TREATMENT

DWIGHT L. WILBUR

---

It is sometimes difficult to appreciate the fact that ill health and disease may result from deficiency or lack of some essential substance. It has been taught for many years that diseases result from an abnormal factor, such as bacterial or other toxins, growth of tumors or trauma, and only in the past forty years has the concept of deficiency disease arisen. Pellagra, beriberi, scurvy and rickets, which now are recognized as deficiency diseases, were at one time thought to be results of intoxications of various types. The later correct concept of deficiency diseases was based on the discovery of those things in foods which are essential for the health of the individual. Clinical and experimental evidence has indicated clearly that vitamins are not only essential for the preservation of health, but that a normal food supply furnishes them in adequate amounts. Although an insufficient intake of protein and certain minerals in the diet will produce states of deficiency, the term is generally used in relation to states of vitamin deficiency.

Most people have become vitamin-conscious, and while physicians in general recognize that disease such as xerophthalmia, beriberi, and scurvy are rare, nevertheless they are constantly reminded, particularly by advertisements, that failure to maintain an adequate intake of this and that food containing vitamins will lead to a variety of diseases. Emphasis is persistently placed on the probability of occurrence of mild states of vitamin deficiency, difficult of recognition, and responding to specific vitamin therapy. Consequently, every wise clinician is continually on the lookout for states of vitamin deficiency among the patients he sees.

There is considerable experimental evidence, substantiated in part by clinical experience that states of partial deficiency

are not uncommon, and that the "optimal" requirement of a vitamin is much higher than the "minimal" or actual requirement.

It is interesting to observe, in the United States at least, that the principal concern with regard to the production of deficiency diseases is not so much because of an insufficient quantity of food as it is because of the preparation of foods in highly concentrated and purified form, such as flour, prepared oils, foods "ready to serve," and so forth. Although such preparation of food has many benefits, it has limited the amount of food taken in the natural state, and it is in the natural state that foods are richest in vitamins. In the past few years the economic depression has, in some instances, reduced the ability of people to obtain foods in a natural state, because many such foods are perishable and therefore expensive.

The importance of the gastro-intestinal tract in relation to the development and occurrence of deficiency diseases is continually being emphasized. It seems reasonable to believe that, in the United States, a considerable proportion of deficiency states will be found to arise as a result of abnormalities of digestion and alimentation. Changes in the gastro-intestinal tract which lead to failure of adequate absorption, no matter what the cause, may lead to deficiency diseases even though the diet contains an adequate supply of essential substances.

#### VITAMIN A

The most readily appreciated clinical symptoms of vitamin A deficiency have to do with changes occurring in the eyes, and consequently in previous years this deficiency has been considered to be manifested chiefly if not entirely in this way, in fact, for years vitamin A was known as the anti-xerophthalmic vitamin since xerophthalmia occurred in vitamin A deficiency.

It seems clear that vitamin A is closely related to the yellow pigment, carotene, which is widely distributed in nature and is found in carrots, squash, yellow corn, and other vegetables. Carotene is the chemical precursor of vitamin A, which is the primary alcoholic derivative produced by the symmetrical division into two parts of the beta-carotene molecule. Vitamin A is probably a catalyst in its chemical action, and physio-

logically it is essential for the maintenance of the integrity and normal state of all epithelial tissues. When vitamin A is present in insufficient quantities the epithelial tissues lose their normal appearance, and thickening or keratinization, followed by secondary infection, result.

**Night Blindness.**—Deficiency of vitamin A may lead to night blindness or inability to see clearly in dusky light; this is not an uncommon occurrence in the Orient but it is unusual in the United States. This condition may be defined as difficulty or inability to adapt vision to faint illumination, and it may result from intra-ocular lesions as well as from deficiency diseases. Jeans and Zentmire have studied the sensitivity to light following partial adaptation to darkness of school children in Iowa, and reported (1934) that about 20 per cent of the children who had subnormal vision in the dark were relieved promptly by partaking of cod liver oil; in a later report (1936) they found that with the same test, 20 per cent of a rural group, 53 per cent of a village group, and from 56 to 79 per cent of an urban group of school children presented evidence of vitamin A deficiency.

**Xerophthalmia.**—This condition is manifested by dryness of the conjunctival tissues which, if it progresses, may lead to conjunctivitis, keratomalacia or softening of the cornea, and finally to blindness. Bitot's spots, triangular white spots appearing like dense foam of soap in the palpebral fissure, and subsequently light brown pigmentation of conjunctiva, may be present during this transition. Xerophthalmia is of exceedingly rare occurrence among infants in the United States.

**Cutaneous Lesions.**—Since the principal influence of vitamin A is on epithelial tissues, it might be anticipated that cutaneous lesions would occur in vitamin A deficiency. The characteristic change, which is considered by some authorities to be the first manifestation of deficiency, consists of keratinization of a hard, dry papular type that resembles goose skin and is most marked on the extensor surfaces of the forearms, legs and thighs.

**Lesions of the Urinary Tract.**—It has been recognized for several years that if an albino rat is given a diet deficient in vitamin A, keratinization of the epithelium of the renal pelvis develops and frequently urinary calculi of the calcium phos-

phate type occur. Although there is evidence to substantiate the view that in some cases renal lithiasis of man may be related to deficiency of vitamin A, nevertheless the exact etiologic relationship cannot be stated until more information is available.

**Infections.**—There has been much discussion of the relation of vitamin A to infections. In fact, this vitamin has been called the anti-infective vitamin, and much of it is prescribed for purposes of combating infections or for increasing resistance to them. The most important practical problem in this respect is not so much whether a person who is receiving an inadequate diet is less capable of resisting infection than is a normal person, but whether an amount of vitamin A in excess of that normally obtained by well-nourished persons will further increase resistance to infection. Since the only recognized anti-infective influence vitamin A possesses is in maintaining normal epithelium which will act as a barrier to infection, and since so far as is known the vitamin does not have any influence on immunologic processes, it seems obvious that vitamin A in reality is not an anti-infective vitamin.

**Miscellaneous.**—Effects of deficiency of vitamin A on tissues other than those already considered have been described. Thickening of epithelial layers of the respiratory and gastrointestinal tracts have been reported, and cysts or acute and chronic inflammatory changes may develop. The relation of vitamin A to changes in the nervous system is questionable. In the experimental animal an insufficient intake of the vitamin may lead to failure of growth, but this apparently is not a significant clinical feature of deficiency of vitamin A in man.

**Diagnosis.**—The clinical diagnosis of vitamin A deficiency is not easy. In the rare case in which xerophthalmia is present, and in which this deficiency is marked, with features noted in the foregoing, the diagnosis may not be difficult if it occurs to the mind of the examining physician. The principal interest at present is detection of states of mild or partial deficiency. When the physician is confronted by a patient whom he suspects may have vitamin A deficiency, he should inquire into the presence of night blindness, and on examining the patient he should look for dryness or pigmentation of the conjunctiva and a papular cutaneous eruption involving particularly the limbs, especially the extensor surfaces. Patients who have

night blindness usually complain that it is impossible for them to see in the twilight, at night, or in a darkened room which they enter from the sunlight. They are likely to bump into objects when walking at night. If examination of the fundus of the eyes does not reveal retinitis pigmentosa or other intra-ocular cause for night blindness, the probability is great that the night blindness is of the essential type and is caused by nutritional abnormalities.

If any of the symptoms noted are present, or if they are absent, and vitamin A deficiency is suspected, two other examinations may aid in determining the presence of this condition. The first is a study of the sensitivity to light following partial adaptation to darkness, as described by Jeans and Zentmire. Such an examination requires special equipment and experience, although if these are available, the test is simple. The second method consists of scraping the bulbar conjunctiva, making smears and examining them for keratinized epithelial cells. If either of these tests is positive or any of the previously noted symptoms are observed, it is reasonable to suspect that vitamin A deficiency is present. Confirmation is obtained if these signs disappear following administration of vitamin A or carotene. Until more satisfactory methods are available for determination of vitamin A in tissues, and until more is known of the physiology of the substance, physicians will have to depend on relatively indirect methods to determine the presence of vitamin A deficiency. If patients have renal calculi or suffer from repeated infections, and vitamin A deficiency is suspected, observations and examinations, as previously noted, may be of some value in suggesting, but not proving the presence of vitamin A deficiency.

**Treatment of Vitamin A Deficiency.**—Deficiency of vitamin A usually may be prevented by the use of adequate amounts of the following foods rich in vitamin A or carotene: butter, cream, cod liver oil, carrots, eggs and spinach. Fish liver oils are rich in vitamin A, particularly those of the halibut, cod, burbot, and tuna.

The daily requirement of vitamin A is not known, but is probably in the neighborhood of 6,000 to 10,000 U.S.P. units. In the treatment of vitamin A deficiency states the following measures are of value: (1) a diet high in content of foods

rich in vitamin A; (2) supplements to the diet of vitamin A in cod or halibut liver oil or carotene in amounts of at least 10,000 U.S.P. units daily; (3) in rare instances by intramuscular injection of cod liver oil or other substances rich in vitamins.

### VITAMIN B<sub>1</sub>

Vitamin B<sub>1</sub>, the antiberiberi or antineuritic vitamin, also known as vitamin B, which has been prepared in crystalline form, is widely distributed in foods. While apparently a catalyst in its chemical activity, physiologically it is essential in the metabolism of carbohydrates, having some part to play, it is thought, in the oxidation of lactic and pyruvic acids. In vitamin B<sub>1</sub> deficiency, there is an abnormality in the pyruvic acid metabolism of nerve tissue which in part is responsible for the disturbances of the nervous system and for degeneration of the peripheral nerves accompanying this condition.

**Multiple Neuritis.**—Deficiency in vitamin B<sub>1</sub> results in multiple neuritis and although it is one of the characteristic features of beriberi, it may occur separately without other features of beriberi, or it may occur in association with other symptoms. There are no clinical features which distinguish the peripheral neuritis of alcoholism from that observed in pregnancy, or in beriberi, or in association with gastro-intestinal disturbances such as chronic diarrhea and vomiting. Recent evidence indicates that in many cases the neuritis which occurs in cases of chronic alcoholism and during pregnancy is the result not of alcohol or toxemia, but of a deficient intake or loss of vitamin B<sub>1</sub> that accompanies these conditions. Efforts have been made to relate many other types of peripheral neuritis to a deficiency of vitamin B<sub>1</sub>, as yet with only partial success.

**Beriberi.**—Beriberi, a disease common in the Orient, is rarely observed in the United States. The characteristic triad of symptoms is edema, peripheral neuritis, and cardiac failure. Although the presence of all of these symptoms would assure the diagnosis, they may not all be present. The cardiac symptoms usually occur as a result of failure of the right side of the heart, which is hypertrophied and dilated. Tachycardia is common, fever is often present, and a variety of the symptoms

may occur, including anemia with macrocytosis of the erythrocytes.

**Changes in the Gastro-intestinal Tract.**—A deficiency of vitamin B<sub>1</sub> has been reported to produce atrophy of the papillæ of the tongue, achlorhydria, and hypotonicity and hypomotility of the musculature of the gastro-intestinal tract. An adequate explanation for these changes is difficult to obtain, although degeneration of Auerbach's plexus may be responsible for the abnormalities in motor function. Anorexia is the most commonly observed gastro-intestinal symptom, but constipation and vague abdominal complaints are not uncommon.

**Changes in the Cardiovascular System.**—Evidence that the cardiovascular system is affected in deficiency of vitamin B<sub>1</sub> is suggested by edema, tachycardia, or bradycardia, which occur in beriberi. Weiss and Wilkins reported that there are certain changes in function of the cardiovascular apparatus in vitamin B<sub>1</sub> deficiency, consisting of simple tachycardia, vagus reflex irritability with bradycardia or with asystole and syncope and failure of the right or left side of the heart, peripheral arteriolar dilatation or vasomotor collapse with vascular constrictions in various combinations. Cardiovascular changes should not be considered as due to vitamin B<sub>1</sub> deficiency unless there is good evidence that the intake of this vitamin has been inadequate or there is associated evidence of the deficiency in other organs.

**Diagnosis.**—The diagnosis of vitamin B<sub>1</sub> deficiency is simple if well-developed beriberi is present. Our particular interest, however, is in states of partial deficiency, and in such conditions the diagnosis is difficult and requires considerable judgment and experience. There are no laboratory procedures which are helpful in determining the adequacy of the vitamin B<sub>1</sub> metabolism of a patient. Recently, Harris and Leong have reported a method by which the vitamin B<sub>1</sub> content of the urine can be estimated quantitatively, but as yet this is not practicable for ordinary clinical use. In some cases in which the diet of the patient is known, an estimation of the adequacy of the vitamin B<sub>1</sub> content of the diet, as compared to the requirement of the patient, may be made by Cowgill's formula. He has shown that the requirement of B<sub>1</sub> is proportional to both intake of calories and body weight.

In searching for clinical evidence of vitamin B<sub>1</sub> deficiency, the physician should keep in mind the symptoms and signs noted in the foregoing, particularly those related to the nervous system and the gastro-intestinal tract. If patients reveal signs of peripheral neuritis, paresthesia of the extremities, tenderness of the muscles with weakness or paralysis, or a sore tongue which may have atrophied papillæ, consideration should be given to the previous diet and to the presence of gastro-intestinal disease which might interfere with adequate nutrition. Great care must be exercised in a given case before attributing anorexia, or other gastro-intestinal symptoms to vitamin B<sub>1</sub> deficiency.

**Prevention.**—It has been estimated that the normal intake of vitamin B<sub>1</sub> for an adult man is 1 mg. daily or 250 to 500 International Units. Since the vitamin is widely distributed in foods, it seems likely that only in cases in which the diet is exceptionally limited will deficiency of vitamin B<sub>1</sub> occur. In cases of chronic alcoholism in which the diet is restricted markedly for a considerable time, deficiency of vitamin B<sub>1</sub> is probably not infrequent. Although there is a suggestion in the work of Williams and his associates that vitamin B<sub>1</sub> deficiency may be far more common than previously has been thought, proof is still lacking. The prevention of vitamin B<sub>1</sub> deficiency lies in the intake of an ordinary well-balanced diet.

**Treatment of Deficiency.**—In the treatment of vitamin B<sub>1</sub> deficiency, a variety of therapeutic methods is available. Foods high in vitamin B<sub>1</sub> content are yeast, fresh vegetables, whole cereals, and milk. Preparations of brewers' yeast in powdered or tablet form, and concentrates and crystals of vitamin B<sub>1</sub> are available for therapeutic use. The crystals may be administered intramuscularly in solution or orally. Spies has emphasized, particularly, in the treatment of pellagra, the advisability of giving exceedingly large doses of vitamin preparations. This same principle probably holds in other vitamin deficiency states. It would be advisable, in a state of vitamin B<sub>1</sub> deficiency, to give 25 gm. of powdered brewers' yeast (such as Harris') one or four times daily, depending on the degree of deficiency, along with a diet containing 4,000 calories and rich in vitamin-containing foods. The minimal therapeutic dose of vitamin B<sub>1</sub> is probably about 10 to 20 mg. daily, and

synthetically prepared crystals are now available at a reasonable cost. One advantage of giving yeast or a similar preparation in place of, or in addition to, the vitamin in crystalline or concentrated form is that, although marked relief is obtained in deficiency states from administration of vitamin B<sub>1</sub> in this form, complete relief is generally not obtained until yeast or some substance containing all the factors of the old water-soluble vitamin B is given. Yeast contains apparently an essential substance which is not present in the crystalline and concentrated forms of vitamin B<sub>1</sub> or in B<sub>2</sub> (G).

### VITAMIN C

Vitamin C, which chemically is ascorbic acid, also known as cevitamic acid, is the antiscorbutic vitamin. More is known of the metabolism of this vitamin than of any other, and in recent years evidence has been accumulating that it is related not only to scurvy but also to dental caries, hemorrhagic diathesis, and anemia. Its relation to acute infections, particularly rheumatic fever, and its place in resistance to infection are uncertain. Vitamin C is a powerful reducing substance, and physiologically is essential in the formation and maintenance, in a normal state, of intercellular substance, particularly of the blood vessels, dental forming organs, and connective tissue.

**Scurvy.**—Scurvy is uncommon in the United States, but it is observed occasionally among infants. The fundamental pathologic change is in the intercellular substance, particularly of the blood vessels and bones, with softening, which leads to hemorrhages into the subcutaneous, subperiosteal, gingival and other tissues. It has been observed that the intercellular substance, which ordinarily exists as a solid or gel, under circumstances of vitamin C deficiency may become a liquid. Early signs in the development of the disease are fleeting pains in the extremities, spongy and readily bleeding gums followed by evidence of hemorrhage into the skin and subperiosteal tissues, particularly of the long bones.

Considerable interest lately has been given to "latent" or "preclinical" scurvy. The clinical features of this condition include dental caries in children, a hemorrhagic tendency which may express itself in hemorrhage from any organ, subcutaneous

petechiæ, a positive capillary resistance test, and a variety of indefinite symptoms, such as fatigue, pallor, underweight, frequent infections, anemia, and fleeting pains in the extremities, which usually are mistaken for rheumatism.

**Dental Caries.**—Dental caries is frequently observed in experimentally produced scurvy, and clinically it has been considered by some observers to be one of the earliest signs of latent scurvy. Vitamin C is essential for the functional activity of certain cells necessary for formation of teeth, especially odontoblasts and cementoblasts, and it prevents their premature degeneration. When insufficient quantities of vitamin C are present, caries may occur. Although it has been suggested by Hanke and others that dental caries is caused mainly by lack of vitamin C in the diet, this opinion is not widely held. The actual incidence of caries from this cause is still not clear, and there are no gross signs characteristic of this type of caries. If the vitamin C deficiency is marked, the adjacent gums may be swollen, red, spongy, and bleed easily.

**Hemorrhagic Diathesis.**—Great interest has been shown in the relation which may possibly exist between vitamin C deficiency and a tendency to hemorrhages. It is well recognized that there is a hemorrhagic tendency in scurvy which is caused, as noted previously, by abnormalities of the intercellular substances of the capillaries and perhaps also by changes in the blood. Whether one can relate, to vitamin C deficiency, isolated or repeated so-called idiopathic hemorrhages from the nose, gastro-intestinal tract, urinary tract, uterus or other tissues, when signs of vitamin C deficiency other than the hemorrhages are lacking is a question much discussed at present, but still unanswered. In this connection there has been much discussion of the capillary resistance test. It still remains to be proved that this measure is accurate in its portrayal of vitamin C deficiency, and it undoubtedly will be superseded soon by estimations of the vitamin C content of the blood and urine and vitamin C tolerance tests.

**Anemia.**—Presnell has noted a reduced number of platelets and anemia, and Minot has emphasized the occurrence of normocytic or slightly macrocytic anemia in states of deficiency of vitamin C. Reticulocytosis of patients with infections following administration of large quantities of vitamin C has been reported by Faulkner.

**Miscellaneous.**—The relation of vitamin C to the endocrine glands and particularly to the suprarenal glands, is still uncertain. Vitamin C is abundant in the suprarenal cortex and medulla, but its direct or indirect relation to the hormones of the suprarenal gland is still not clear. There has been considerable interest in the possible relation between vitamin C and infections, particularly rheumatic fever and perhaps chronic infectious arthritis. Although changes in the joints similar to those observed in these conditions have been observed in animals which receive diets deficient in vitamin C, there is much evidence against a direct etiologic relationship between deficiency of vitamin C and rheumatic diseases. The clinical value of vitamin C in combating infections of any type is still uncertain, although laboratory evidence suggests that the vitamin may have certain detoxifying properties.

**Diagnosis.**—The diagnosis of scurvy is relatively simple in a well-developed case. The spongy, bleeding gums, painful extremities, and evidence of subperiosteal, subcutaneous, and other hemorrhages are diagnostic signs. The diagnosis of latent or preclinical scurvy is difficult, but suspicion should be aroused if patients reveal considerable dental caries, have unexplained hemorrhages of any type or in any situation, or have long-continued infections. Persons who have used little citrous fruit, tomatoes, milk, and fresh fruits and vegetables may have, or may develop, latent scurvy. It is exceedingly important to emphasize that such conditions do not establish the diagnosis, but only suggest the possibility of it.

Fortunately, physicians possess better methods of determining the presence or absence of partial deficiency of vitamin C than of any other vitamin. The use of capillary resistance tests, estimations of the content of vitamin C in the blood and urine, the use of vitamin C tolerance tests, and estimations of vitamin C saturation are all valuable in this connection. In addition, a therapeutic test in which ascorbic acid is given may produce presumptive evidence of previous deficiency of this vitamin.

If the physician will bear in mind the symptoms previously enumerated as occurring in vitamin C deficiency, the first step to a diagnosis will have been made. The next step perhaps is performance of the capillary resistance test. This is rela-

tively simple and can be performed in the office by marking an area on the skin, 60 mm. in diameter, in the antecubital fossa of one forearm. Following this, venous stasis is produced for fifteen minutes with a sphygmomanometer cuff at a pressure of 50 mm. of mercury. If more than eight petechiæ develop on the marked area, the test is positive; if less than five develop, it is negative. Although this test is not specific, it is suggestive, and, if positive in a case in which vitamin C deficiency is suspected, it should lead to studies either of vitamin C saturation or a therapeutic trial with vitamin C. The quantitative estimation of vitamin C in the urine is relatively simple and can be performed after the method of Harris and Ray with the indicator, dichlorophenolindophenol. At present data are insufficient to permit evaluation of the estimation of vitamin C in the urine excreted during twenty-four hours. The amount excreted depends on the intake and on the saturation of the tissues. Youmans and others reported that an excretion of 20 mg. of vitamin C per day is the lower limit of normal in adults. Estimation of the vitamin C content of the blood is still of uncertain value. Although Abt and his associates expressed the belief that the values they obtained for the reduced cevitamic acid content of the blood plasma will prove a convenient, rapid and accurate method for the detection of subclinical scurvy, this opinion remains to be confirmed. Probably in the future the use of tolerance tests, or of methods of determining the saturation of the tissues with vitamin C will prove most valuable in determining latent scurvy. For example, Youmans has estimated that if a test dose of 600 mg. of vitamin C is given, at least 30 per cent should be excreted in the urine of a normal individual in twenty-four hours. Further observations are necessary before standards are established in this rapidly developed field.

**Prevention.**—Scurvy or vitamin C deficiency may be avoided by intake of a diet adequate in fresh fruits, particularly of the citrous variety, and vegetables. In infants, this is readily accomplished by the almost universal use of orange juice or a substitute. The minimal intake of vitamin C necessary to prevent signs of deficiency is not certain, but probably approximates 20 mg. daily. Occasionally much larger quantities apparently are necessary; it was necessary to give one patient 200 mg. daily to prevent hemorrhagic tendencies.

**Treatment of Deficiency.**—The diet should be high in its content of fresh vegetables and fruits, particularly citrous fruits. This may be supplemented by the administration of vitamin C, in synthetic crystalline form, by mouth or intravenously; from 50 to 200 mg. or more daily should be sufficient in therapy. When given intravenously, solutions of the sodium salt of cevitamic acid approaching approximate isotonicity can be used; that is, 1 per cent of the salt dissolved in physiologic salt solution or 3 per cent dissolved in distilled water. If only the acid is available, it should be neutralized with half its weight of sodium bicarbonate in physiologic salt solution or water before it is injected.

### VITAMIN D

Vitamin D, which is the antirachitic vitamin, is probably the one best known by the layman because it is widely advertised. Rickets is such a widespread disease of infants in the northern hemisphere that it could be classified as probably the most common deficiency disease. Seven chemical substances have been shown to possess vitamin D activity, and consequently the vitamin is not a single chemical substance. Physiologically, the vitamin plays an essential part in the metabolism of calcium and phosphorus, having to do with the retention of calcium and phosphorus in the body as a whole, in the deposition of calcium and phosphorus in the bones, and perhaps in the concentration of these elements in the blood. Calcium, phosphorus, vitamin D and parathyroid hormone are essential for mineralization of normal bone, and the individual part played by each in this metabolic process is still not clear.

**Rickets.**—Deficiency of vitamin D results in rickets, and it has been stated that from 50 to 90 per cent of infants have signs of rickets. The fundamental fault in this disease is failure of adequate mineralization of the bones. The earliest symptoms are usually restlessness, irritability, and head sweating, which are followed by enlargement of the costochondral junctions and formation of the "rachitic rosary." The head may become enlarged and square, the fontanels may remain large, and softening of the parietal bones often results. The epiphyses of the wrists are often enlarged. Weakness of the

muscles, tardy dentition, and spinal curvature may be accompanying signs. The roentgenologic features of the long bones are characteristic; they are first observable at the lower epiphysis of the ulna and femur, and consist of broadening and concavity with irregularity of the epiphysis. There is less density or calcification of the bone than in the normal. Characteristic changes in the chemical constituents of the blood may occur, with decrease in the percentage of inorganic phosphate.

**Osteomalacia and Osteoporosis.**—Osteomalacia or adult rickets has frequently been reported in China but is not observed in the United States. Osteoporosis, however, is not of infrequent occurrence, but it is difficult to judge in the isolated case if it results from abnormality of calcium, phosphorus, parathyroid, or vitamin D metabolism. Not infrequently, in association with celiac disease, there may be osteoporosis, secondary probably to interference with absorption from the bowel of calcium or vitamin D. The recognition of osteoporosis depends entirely on roentgenologic examination. It frequently is associated with pain in the spinal column and shortening of the body height.

**Tetany.**—Tetany may accompany rickets, or it may be associated with celiac disease or sprue which interferes with absorption of calcium, phosphorus, and vitamin D. Tetany, however, is not the result of vitamin D deficiency exclusively. When osteoporosis and low serum calcium accompany tetany, the diagnosis is most likely tetany caused by insufficiency of calcium or of intake or absorption of vitamin D.

**Dental Caries.**—There is little doubt that vitamin D is essential to normal dentition. An inadequate intake of vitamin D is considered by some workers as the most frequent cause of dental caries. An insufficient intake of vitamin D is not the only mechanism by which dental caries is produced, since caries may occur when intake of vitamin D is adequate.

**Diagnosis of Vitamin D Deficiency.**—The diagnosis of rickets is usually simple. When the classical symptoms are present, the diagnosis is obvious clinically. In cases in which the symptoms are less clear cut, the diagnosis may be suspected clinically and confirmed by roentgenologic studies of the long bones.

States of partial deficiency of vitamin D may be suspected if persons have dental caries, tetany, frequently occurring fractures, and osteoporosis of the bones. Patients who have abnormalities of intestinal absorption, such as occur in celiac disease, sprue, and so forth, may present such a deficiency. Whether it is the result of deficiency of calcium or phosphorus or of abnormalities in function of the parathyroid glands may be difficult to determine. The administration of vitamin D may be helpful in distinguishing osteoporosis which is on a basis of deficiency from other types, but it does not necessarily prove that it is attributable to deficiency of vitamin D alone.

It is probable that states of vitamin D deficiency are extremely uncommon among adults.

**Prevention.**—Vitamin D is specific in the prevention of rickets. It may be administered as cod liver oil, viosterol, irradiated milk, or cereals, or by irradiation of the skin by ultraviolet light. Shelling and Hopper reached the conclusion that five drops of viosterol containing about 1,125 U.S.P. units of vitamin D is efficacious in preventing rickets. Jeans reported that an animal source vitamin D in the amount present in one standard teaspoonful of average high-grade cod liver oil or in milk containing 400 U.S.P. units to the quart (1,000 c.c.) is adequate for the infant from the standpoint of retention of calcium and growth.

**Treatment.**—Vitamin D can be administered in a variety of ways. It may be given in fish oils, such as cod liver oil (viosterol), and in a variety of foods, milk, cereals, and so forth. Irradiation of the skin with ultraviolet light will produce vitamin D in the skin, and is useful for the prevention and treatment of rickets. Foods which contain ergosterol, such as milk and cereals, can be irradiated before ingestion, and vitamin D activity may be obtained. Application of vitamin D to the skin results in absorption and utilization of the vitamin.

Therapeutic doses of vitamin D in treating rickets may be in the neighborhood of 20 drops of viosterol (4,500 U.S.P. units), or a similar number of units in other form. In adults with senile osteoporosis, 10 drops of viosterol three times daily in conjunction with 4 gm. of calcium lactate or tribasic calcium phosphate three times daily often will relieve symptoms.

VITAMIN G (B<sub>7</sub>)

Since the demonstration that the original water-soluble vitamin B is composed of several separate fractions, there has been much interest in the character and physiologic properties of the heat stable or antidermatitic factor, B<sub>2</sub> or vitamin G.

For years this vitamin has been mentioned as of etiologic significance in pellagra. Within the last year it has been demonstrated that vitamin G is in fact two substances: one a flavine and the other a supplementary substance contained in yeast extracts and identical with György's vitamin B<sub>6</sub>. The physiologic functions of these two fractions are still not clear; apparently neither alone possesses the growth-promoting action which together they manifest. Recent evidence suggests that the pellagra-preventing factor is the supplementary substance of vitamin B<sub>6</sub>. Singly or together, the two factors are essential for normal functioning of the skin, nervous system, and gastro-intestinal tract.

**Pellagra.**—The etiology of pellagra is still not clear. That a dietary fault exists in most cases seems certain, but whether or not such a faulty diet is the exclusive etiologic agent has not been proved. While it has been generally accepted that pellagra associated with chronic alcoholism, or so-called alcoholic pellagra, is due to inadequate diet, eminent clinicians have previously failed to accept the likelihood that so-called endemic pellagra in the South was exclusively a deficiency disease. However, recent observations of McLester, Spies and their associates indicate that probably most if not all cases of endemic pellagra may be controlled or cured by dietary measures. Although pellagra is common in the South it is not often observed in the North, and when it occurs is often in association with chronic alcoholism and organic disease of the gastro-intestinal tract. This type of pellagra, secondary pellagra, has been noted by Eusterman and O'Leary and other workers, and is of serious prognostic importance, particularly if surgical treatment of a gastro-intestinal lesion is contemplated.

The diagnosis of pellagra still rests on the triad of three d's—dermatitis, diarrhea, and dementia, but these occur simultaneously in severe cases only. Perhaps the most characteristic

feature is the dermatitis, without which the diagnosis is difficult and questionable. The cutaneous lesions consist of dermatitis suggesting sunburn, a reddened, dirty-brown skin, parchment-like, rough and scaly, affecting principally the exposed surfaces, especially the backs of the hands, wrists and forearms, usually in a symmetrical fashion. The face, neck, genitalia and legs may be similarly involved. Gastro-intestinal symptoms which accompany pellagra are variable; diarrhea is the most common in advanced cases and it may be intractable. In less severe cases there may be flatulence, anorexia, vague abdominal distress and at times constipation. Achlorhydria is a frequent finding. Nervous symptoms are not at all uncommon and while dementia is characteristic of severe pellagra in the less severe forms, symptoms characteristic of neurasthenia, such as exhaustion, lassitude, and insomnia, may be present. Loss of weight is characteristic. The development of any of these symptoms, when accompanied by dermatitis of the type mentioned, should suggest the possibility of pellagra. It is wise to examine the stomach and colon of patients for evidence of organic disease if they have pellagra and apparently have been on an adequate diet, or who because of gastro-intestinal symptoms are unable to eat normally. Not infrequently obstructing lesions, particularly malignant ones, or evidence of ulcerative colitis will be found.

**Treatment.**—Despite variability in opinion as to its etiology, the treatment of pellagra is chiefly dietary. The rapid strides which have been made in this respect are well illustrated by Spies, who reported that in the Lakeside Hospital, Cleveland, from 1926 to 1930, 54 per cent of seventy-three patients with pellagra died, despite good care in the hospital. During the past five years Spies and his associates have been able to reduce the mortality to 5 per cent or less among persons who have severe pellagra. The diet should be adequate, the patient should rest, and symptomatic measures should be instituted. In the dietary treatment, Spies has emphasized the importance of very large amounts of foods and preparations high in content of vitamins.

Foods particularly rich in vitamin G are fresh vegetables, especially leafy ones, milk, cream and eggs. Beef, potatoes, and citrus juices are good sources of the vitamin. Yeast and

yeast extracts are especially rich sources of vitamin G, which is also found in liver extract for parenteral use.

In some cases in which vomiting is not present, Spies suggested the use of a well-balanced diet containing 4,000 calories or more, and in addition good brewers' yeast, wheat germ, or liver extract. Good brewers' yeast or wheat germ may be given in doses of 10 to 20 gm. in iced drinks at intervals of three to four hours to make a total of 75 to 100 gm. daily. Liver extract given parenterally in from three to five doses of 20 c.c. each daily is specific, and although expensive is of especial value for patients who, because of a sore mouth or vomiting, cannot tolerate an adequate diet.

Adequate rest with hospital and nursing care is essential in the treatment of severe pellagra. Symptomatic treatment consists of the use of sedatives, antiseptic solutions, such as potassium permanganate, 1:5,000, applied to the skin and tincture of opium in large doses to control diarrhea.

In milder cases in which the diagnosis is uncertain or questionable, the diet should be high in vitamin content and supplemented by 1 ounce (30 c.c.) or more of brewers' yeast or wheat germ, or liver extract given parenterally in doses of 10 c.c. daily.

For patients with organic disease of the digestive tract and pellagra, and for whom surgical treatment is contemplated, the pellagra should be treated before any operative procedures are carried out. Such patients do not stand operations well. The use of liver extract parenterally is of particular value to these patients, since it permits administration of vitamin G without disturbing the gastro-intestinal tract and since the action is rapid.

## THE MANAGEMENT AND TREATMENT OF THE HEART IN SENESENCE

FREDRICK A. WILLIUS

---

THE problem of heart disease among persons of advanced years presents certain aspects that are different from those of heart disease in general. In the first place, the problem is narrowed down to a very small group of individuals who selectively have been spared from earlier death from many possible causes. In the second place, the deletion process has greatly reduced the forms of cardiac disease that affect persons of advanced age. Finally, the management of the senescent patient is ordinarily less difficult than is that of younger patients; in the former instance, age has already imposed the necessity of certain physical restrictions, the problem of earning a living has frequently been solved, and there are few, if any, dependents.

It is necessary to establish definite criteria as to what constitutes a normal heart in the late years of life. If one adheres to the criteria which some pathologists have advanced for a normal heart, only the occasional venerable could possibly qualify for a place among this select company. I believe it is only just to recognize the fact that the criteria established for the normal heart at a given period of life must necessarily be modified to meet the dissimilar circumstances at another period. The cardiovascular system, like many other components of the body, participates in a metamorphosis as the succeeding decades of life are encountered. The passage of time and the sustained effect of continuous function, in addition to the variable supplemental stresses and strains of life, inevitably bring about changes in all living things. The most common effects, so far as the heart is concerned, are the sclerotic changes of the coronary arteries and the increased work imposed on the left ventricle by the frequent association of varying degrees of hypertension.

Postmortem examination of patients who are seventy years of age and older practically always reveals evidence of coronary sclerosis. However, these sclerotic changes very frequently are not obliterative in character, and unless obstruction occurs, they may not seriously handicap the function of the heart, especially when the individual has geared his tempo of activity to a level commensurate with his age. The general biologic process of senescence often proves to be a subtle mechanism of self-preservation.

The study of a series of 3,418 cases furnished fairly accurate statistics with reference to the incidence of the eight principal forms of heart disease in the ten decades of life. The forms of heart disease included in this analysis were coronary disease, hypertensive heart disease, rheumatic heart disease, syphilitic heart disease, adiposity of the heart, chronic adherent pericarditis, calcareous aortic stenosis, and congenital heart disease. In 10.7 per cent of the cases the patients were in the eighth, ninth and tenth decades of life; the majority of these patients had coronary disease or hypertensive heart disease. Coronary disease occurred in 5.6 per cent, hypertensive heart disease occurred in 4.4 per cent, while the other forms of heart disease combined occurred in only 0.7 per cent of the entire series of cases.

The sex incidence of cardiac disease which affects senescent individuals is not only of interest but is important. Two separate studies revealed a great preponderance of male patients; in each series of cases the ratio of males to females was 5:1. This discrepancy in sex incidence was to some degree explained by the fact that the number of elderly males who come to the Clinic is greater than the number of elderly females; this is partially explained by the fact that a large number of the elderly men come to the Clinic because of prostatic hypertrophy.

Varying degrees of hypertension is the rule among aged patients; in a study of 700 patients who were seventy-five years of age and older, the value for the systolic blood pressure was found to be 140 mm. of mercury or more in 70.3 per cent of the cases and that for the diastolic pressure was found to be 90 mm. or more of mercury in 40.3 per cent of the cases.

In order to portray the actual pathologic findings in the

senescent heart it seems appropriate to summarize the findings reported in a previous study which was based on the post-mortem findings in 381 cases in which the patients were seventy years or more of age. These cases were selected from a group of 5,751 cases in which the patients came to necropsy. The selection was based on the age of the patients.

Some degree of coronary sclerosis was evident in all of the cases while moderate to advanced degrees of coronary sclerosis were revealed in 72.5 per cent of the cases. Fairly definite parallelisms between the degree of coronary sclerosis and aortic sclerosis occurred, although rather wide variations occurred in individual cases.

Varying degrees of valvular sclerosis occurred in 92.7 per cent of the cases. The valves of the left side of the heart were involved much more frequently than were those of the right side. The mitral and aortic valves were involved in 86.1 per cent of the cases, whereas the tricuspid and pulmonic valves showed involvement in only 13.9 per cent of the cases.

Healed cardiac infarcts were discovered in 4 per cent of the cases and acute cardiac infarcts which had caused death soon after their occurrence were found in 2.9 per cent of the cases.

Occasionally one sees an extremely old patient who has survived coronary thrombosis. In a case recently observed, the patient was a man aged ninety-two years, who had had an attack of coronary thrombosis several months previously, but still was found to be in surprisingly good condition.

Evidence of old, healed endocarditis was disclosed in 3.9 per cent of the cases, but in only 1.1 per cent of the cases was the process marked. Pericarditis occurred in only 3.1 per cent of the cases. This included instances of chronic adherent pericarditis and acute and chronic fibrinous pericarditis. Acute bacterial endocarditis, an incident in generalized sepsis, occurred in 1.3 per cent of cases, syphilitic aortitis occurred in only 0.8 per cent of the cases and in one case carcinoma had metastasized to the myocardium.

It thus becomes evident that the problem of the heart in senescence is chiefly concerned with arteriosclerotic heart disease and hypertensive heart disease, and with their coexistence.

In the management of aged patients the physician must exercise an abundance of tact and diplomacy. He should not

disturb the habits and customs of a long life until he has unmistakably ascertained their detrimental influence. Even then, gradual modification and compromise may be the subtle and successful way of accomplishing the purpose desired. Complete and prolonged rest in bed should be avoided except in the presence of congestive heart failure and acute cardiac infarction, as it is a well-established fact that elderly patients are very intolerant to complete invalidism.

Ridiculously strict dietary impositions are undesirable unless such diseases as diabetes, nephritis and so forth demand drastic changes in the usual intake of food. Marked reduction in diet in order to correct obesity is likewise an undesirable procedure in the senescent period of life. The restriction of fluids is also undesirable unless congestive heart failure with its attendant retention of fluid exists.

In the medicinal treatment of heart disease which affects aged patients, caution must be used in the administration of certain medicinal agents, particularly digitalis. It is a well-known fact that old people do not tolerate the administration of digitalis well and that symptoms of intoxication are likely to appear after the administration of doses that ordinarily would not induce such phenomena among younger patients. This not only applies to such well-known symptoms as anorexia, nausea and vomiting, but particularly to the signs of cerebral intoxication and also to disturbances of cardiac rhythm and conduction. The indiscriminate administration of digitalis to patients of all ages is to be condemned, but its unnecessary employment in the senescent period of life is an unpardonable error. The chief indication for administration of digitalis is congestive heart failure, especially when auricular fibrillation with rapid ventricular rate is present or when the latter is present without cardiac failure.

Likewise, the use of salyrgan should be carefully controlled; however, its skillful employment in congestive failure has repeatedly proved of inestimable value. The determination of renal adequacy is always desirable, whenever possible, before salyrgan is used. A word of warning is desirable regarding the administration of this diuretic to elderly men. It must be remembered that many senescent men have hypertrophy of the prostate gland with partial urinary obstruction and that under

conditions of profuse diuresis urinary obstruction may become complete. Thus, particularly when the urinary output is not considerably increased, careful palpation of the suprapubic region may reveal a greatly distended urinary bladder. Under these circumstances, the introduction of an indwelling catheter becomes necessary.

From time to time, elderly patients who have congestive heart failure may be literally dehydrated in spite of their water-logged condition. The prompt recognition of this fact is of utmost importance, for this situation demands the introduction of fluids in such a manner that they will be rapidly available. It is in such cases that the extremely slow injection of a hypertonic solution of dextrose into a vein is of great value. Dextrose is administered in quantities of 300 to 500 c.c. of a 15 to 20 per cent solution and may be injected into a vein daily or twice daily for several days.

Administration of dextrose likewise has an important place in the treatment of paroxysmal dyspnea. This troublesome symptom frequently accompanies both coronary disease and hypertensive heart disease, which affect the aged patient. The beneficial effect of dextrose is theoretically based on the fact that it replaces glycogen, which is an important constituent of heart muscle. Glycogen is rapidly mobilized under conditions of anoxemia.

Morphine is an extremely valuable drug in the treatment of heart failure; its ability to produce rest and profound sleep in a case in which the patient is restless and wakeful is well known. However, it should be administered cautiously to a senescent patient who has heart disease as it occasionally produces untoward effects. I have from time to time observed Cheyne-Stokes breathing while the patient was under the influence of the drug, but this disappeared promptly when the action of the drug became dissipated. Smaller doses than ordinarily used are desirable and less frequent repetition of the dose is indicated in such cases.

Likewise sedatives such as the barbiturates, amytal and so forth should be administered judiciously, owing to the fact that a mild delirium may occur while the action of the drug endures. The inevitable occurrence of varying degrees of cerebral arteriosclerosis among elderly patients is probably the determin-

ing factor in the production of these undesirable effects. Under these circumstances, the administration of the tincture of opium in moderate doses or the use of chloral hydrate frequently is a satisfactory solution to the problem.

The purine derivatives, such as theobromine, theocin, theophylline, metaphyllin and aminophyllin, can be safely used in such cases when indicated, just as they can in other cases in which the patients are young.

It is, of course, necessary to restrict the physical activities of elderly patients. As previously stated, senescence frequently accomplishes this through such handicaps as arthritis, disturbances in vision and so forth. However, numerous patients are encountered who, through the enthusiastic yet misguided advice of their friends, are encouraged deliberately to seek exercise, and who, with the gusto of the true believer, indulge in ridiculous exertion which is very hazardous and unbecoming to their venerable position in life. There is no doubt that this misguided enthusiasm on the part of many elderly patients results in sudden cardiac death or prolonged heart failure and ultimate death.

In this connection it may be appropriate to recall the story of the old man who had lived for ninety-eight years and whose philosophy of life is recorded in the following narrative. A solicitous friend inquired as to what the old gentleman attributed his longevity. After his usual deliberation he replied as follows: "I never stood when I could sit, I never walked when I could ride and I never stayed awake when I could sleep. In fact the only exercise I indulged in was to be pall-bearer at the funerals of my exercising friends." This point is perhaps well taken, although fictitiously exaggerated.

Nevertheless, with the inevitable premise before us, life is a biologic metamorphosis and the individual who deliberately seeks great longevity, a questionably desirable goal, must voluntarily gear his activity and enterprise to the ever-changing conditions of advancing years. I believe that most people do not seek an endurance record of this type, but desire to participate constructively in life and are only too willing to accept the hazards of such a philosophy.

## DIGITALIS: ITS RATIONAL USE

FREDRICK A. WILLIUS

---

NOTWITHSTANDING the fact that digitalis has been used by physicians for a century and a half it is probably the most misused drug in the practice of medicine. Since the days of William Withering, digitalis generally has been conceded to be the most important and the most valuable drug in the treatment of heart disease. The main reason for its misuse probably lies in the fact that we have not as yet thrown off the bonds of empiricism. We have been taught that digitalis is the sovereign remedy in heart disease, and we have been taught also its actions, its methods of administration, and certain dangers regarding its use. Our chief impression regarding digitalis is based largely on the experience that certain patients with heart disease are greatly benefited by the use of the drug. However, if we analyze our experiences with digitalis more fully, we soon recall the fact that we have frequently been puzzled when good results from its administration have not been forthcoming.

The beneficial effects of digitalis in heart disease result from changes the drug produces in the various functions of the cardiovascular system. Many actions have been assigned to digitalis, and many of these have not withstood the test of time and experience, a fact which has undoubtedly contributed to the existing confusion as to its actions and indications. The effect of digitalis on the diseased heart of man is narrowed down to three definite actions, the understanding of which greatly simplifies the indications and contraindications for its use. These three actions are: 1. It depresses the function of the sino-auricular and auriculoventricular nodes, resulting in a tendency to slow the cardiac rate. This is, in part, a vagal action. 2. It depresses cardiac conduction throughout the muscle and increases the refractory period of both the auricles and the ventricles. Depression of conduction, particularly

through the auriculoventricular bundle (His), occurs; this explains the striking effect of the drug in many cases of auricular fibrillation. 3. It increases the amplitude of cardiac contraction. It tends, also, to restore tonus, apparently because of its direct action on heart muscle.

Digitalis does not exert a constant effect on blood pressure; a rise may occur as part of the improvement of cardiac function and general circulation. Likewise, its effect in the production of diuresis is not a result of stimulation of the renal epithelium, as was formerly believed, but again results from the more normal behavior of the renal and the general circulation.

The effect of digitalis on the diseased heart is very different from its action on the normal heart, and also from its effect on the heart of the experimental animal. In order to comprehend the action of digitalis on the impaired heart it is necessary to analyze critically the various actions that the drug may exert, and also to comprehend fully the various underlying disorders leading to heart failure.

Considerable difficulty is at times encountered in definitely establishing the basis of heart failure, and not infrequently failure results from a combination of conditions that must be determined in their proper relationships. The physician is often too willing to rest after he has satisfied himself that a failing heart is the cause of the patient's symptoms, and he may make little, if any, attempt to identify the type of lesion. One of the most important factors in the misunderstanding regarding heart disease and its management has been this apparent indifference to determining the etiologic factor or factors responsible for the existing cardiopathy.

The preparations of digitalis most commonly used are derived from the leaves of *Digitalis purpurea*, although preparations from the leaves of *Digitalis lutea* have been used and are presumed by some to have less tendency to produce nausea and vomiting.

A tincture of digitalis of established potency and of known date of manufacture is a very satisfactory preparation. Its administration is simple, and conveniently permits changes in dosage.

The infusion is the oldest of the preparations of digitalis.

It has been found to be an unreliable preparation, when made by accepted methods, owing to its instability and to the great variations in its potency. Some pharmacists prepare the infusion from the fluidextract, which results in a product of a potency totally different from that of the official infusion and which is no longer comparable to it. An infusion made from the fluidextract has a greater digitoxin content than the official infusion. The relative value of the standard tincture and of the infusion of digitalis has been investigated by Weiss and Hatcher. By their method an infusion of digitalis was prepared that in all respects compared favorably with the standard tincture, and when it was kept in completely filled, hermetically sealed bottles it remained unaltered for nearly two and a half years.

The use of powdered leaves of digitalis in capsules and standard tablets are also satisfactory methods of administering the drug.

Digitalis may be administered intramuscularly or intravenously, although indications for the employment of these routes are less frequently encountered. These methods of administration usually presuppose the presence of an emergency in which the physician has had little or no time for the careful analysis of his patient. It is always possible in a case of acute heart failure that the basis of the condition might definitely contraindicate the use of digitalis. The intramuscular and the intravenous method may be employed with safety when the clinical status of the case is well established, but in the majority of instances it has little advantage over the oral method of administration. Pardee has pointed out that the promptness in action which follows injection is more dependent on the large size of the dose given than on the greater promptness with which the drug comes in contact with the heart muscle. My experience has put me in full agreement with this statement.

Clarke, in a comparative study based on the rate of slowing caused by digitalis, showed that an effect was evident within three to four hours after intravenous administration, in about four hours after intramuscular administration, and in about six hours after oral administration.

There is no reliable evidence that proprietary preparations of digitalis have any advantage over official preparations.

The use of compound tablets containing digitalis in combination with other drugs is to be condemned, as analysis of their constituents so often reveals the presence of these drugs in such ridiculously small amounts as to be pharmacologically inactive.

Studies dealing with the absorption of digitalis from the alimentary tract of man have been carried on by several investigators. It has been shown that the galenical preparations of digitalis are absorbed with sufficient uniformity to allow the establishment of an average, total therapeutic requirement of the drug, even for samples from various sources and of different activity. Eggleston and Wyckoff showed that a satisfactory, average total dose, expressed in terms of the "cat-unit" of activity for each pound of the patient's weight, was possible when high-grade tinctures were used. The absorption of average tinctures was variable. High-grade tinctures, in sufficiently large doses, revealed definite action on the heart of man within two to four hours after oral administration. Tinctures of less activity required five or more hours for their effects to become manifest.

It must be clearly understood that the first evidence of the action of digitalis does not imply the full therapeutic effect, as this is rarely obtained in less than twenty-four or forty-eight hours, and then only when larger doses are employed.

In the administration of digitalis the difficulty encountered at times in establishing a method whereby the patient is sufficiently held under the action of the drug without eliciting the toxic symptoms of overdosage is well known. The rate of elimination from the body or the degree of destruction in the body have been unknown quantities.

Pardee, in studying the rate of disappearance of digitalis from the body, found that approximately 0.1 to 0.2 gm. is lost in twenty-four hours. These results would imply that at least 0.15 gm. (1.5 c.c.) would be the required daily dose necessary to maintain a digitalis effect after the full therapeutic effect had been obtained.

The establishment of the diagnosis of heart disease is frequently considered the indication for the administration of digitalis. Such a criterion is absolutely fallacious and frequently results in serious difficulty. No method of treatment is attended by greater hazards than the indiscriminate and improper administration of digitalis.

The two striking indications for the employment of digitalis are the presence of congestive heart failure and the presence of auricular fibrillation with rapid ventricular rate. This statement requires modification, as at times in rapid auricular fibrillation the administration of the drug must be cautious or, perhaps, it must be withheld. As previously stated, the establishment of a definite diagnosis of the type of lesion is of primary importance.

The exhibition of digitalis, in cases of acute heart failure, before the exact cause for the failure is determined is not without danger. Heart block, sudden failure from coronary occlusion, and intense hyperthyroidism, especially if crisis is present or impending, are clear-cut contraindications to its use.

The presence of auricular flutter invariably demands medication with digitalis, and often very large doses and prolonged periods of administration are necessary and are well tolerated. These observations suggest that the elimination of digitalis in flutter is perhaps more rapid than in other disorders of cardiac action.

In general, although this statement is not without exception, digitalis is more effective for young and middle-aged patients, especially those with the heart failure of valvular disease, than for older patients with hypertensive, coronary, or syphilitic cardiovascular disease.

There is no doubt that digitalis may be of benefit in cases of failure when the cardiac rhythm is regular. This fact was emphasized by Christian and I believe has been the experience of all who have used digitalis.

My experience with digitalis has led me to be cautious in its administration to older patients, and has led me to give moderate doses over periods that have not been too prolonged.

One of the signs of excessive administration of digitalis is the appearance of premature contractions or extrasystoles. When caused by digitalis, they usually occur paired with the normal beats and result in the so-called coupled rhythm. The presence of premature contractions, however, occurring in a case in which the patient has not received digitalis recently must not be considered as a contraindication for the exhibition of this drug.

Digitalis has little or no value in paroxysmal tachycardia.

The preoperative digitalization of patients with cardiac disease is to be condemned as a routine practice. Several objections to this become evident at once. In the majority of instances, the preoperative administration of digitalis is unnecessary and involves, therefore, an unnecessary loss of time for the patient, with the attendant financial burden. As previously stated, many older patients do not tolerate digitalis well, and if it is indiscriminately given, they may be in a less favorable condition to meet operation. If it is recalled that little can be anticipated from the exhibition of digitalis except in cases in which heart failure is present or has recently been present, the chief contraindication to this procedure becomes evident. If heart failure exists, operative intervention is positively contraindicated, and then only after cardiac function has been re-established by proper treatment.

It is my belief, therefore, that the indications for the routine preoperative digitalization of patients with heart disease lack scientific and clinical confirmation, and that this routine should be discouraged.

Likewise, the routine administration of the drug in cases of pneumonia is not to be encouraged. Controlled studies have failed to demonstrate any justification for continuance of the procedure. When heart disease and pneumonia coexist, and the situation is such that under ordinary circumstances the heart would demand digitalis, or the additional load imposed by pneumonia threatens heart failure, it should be employed intelligently. We must not lose sight of the fact that the patient with pneumonia may be extremely toxic, and that the addition of a toxic drug in a full therapeutic dose may lead to disaster.

As previously stated, the oral method of administration of digitalis is the one of choice. Many patients have failed to receive benefit because too little digitalis has been given; less frequently, harm has resulted from its administration in excessively large doses.

Eggleston demonstrated the possibility of giving relatively large doses of the drug, and his method of administration is known as the Eggleston method. The strength of the preparation employed is determined in cat units, and from this the dose is calculated for man. When the standardized tincture is used, the average requirement in oral administration for production

of the full therapeutic effect or minor toxic action is about 0.146 c.c. for each pound of the patient's weight. For example, a patient weighing 150 pounds (68.1 kg.) would require 21.9 c.c. of the tincture. The calculated total dose is given in divided portions: the first dose is half the total dose; the second, which is given six hours later, is half the remainder, and the third and fourth doses, given at intervals of six hours, are half the second dose.

Eggleston's method has been modified in numerous ways, although the general principle of the method has been maintained.

These methods of administering relatively large doses of digitalis over short periods are not without objection. Their justification implies that the patient has been carefully examined and that the cause of heart failure has been fully determined. After the total calculated dose has been given, means do not exist whereby the action of the drug may be modified, and notwithstanding various opinions the onset of toxic symptoms is highly undesirable, and at times, hazardous.

In the majority of cases of cardiac disease in which digitalis is indicated, sufficient time may safely be consumed to administer smaller individual doses over a longer period of time. Experimental studies have shown that full therapeutic effects, without toxic symptoms, can be obtained with standard preparations in doses of 1.5 gm. (22 grains) of the leaf, or 15 c.c. (225 minims) of the tincture. These therapeutic effects may be obtained even if digitalis has been employed in the same case; however, at least two weeks without digitalis must be allowed to elapse between the two periods of administration of the drug. The administration of 1 to 1½ grains of the leaf or 1.5 to 2 c.c. of the tincture three times daily is a satisfactory and safe method in most cases.

After the development of the therapeutic effect, the problem of maintaining the action of digitalis without the onset of toxic phenomena presents itself. Numerous methods of administering the drug have been employed, but in general two plans are adopted. Digitalis may be given daily, in doses sufficiently large to maintain its effect over relatively long periods of time; or larger doses may be employed, and may be given for a few consecutive days each week with regular periods of withdrawal.

In order to obtain satisfactory results, the method of administration must be selected to meet the needs of the individual case. In my experience, the second method has proved satisfactory. The individual dose, administered three times daily for the necessary number of consecutive days each week, is readily adapted to varying conditions.

The daily administration of ridiculously small doses of digitalis is without scientific support and should not receive encouragement.

It is important to emphasize the great discrepancies in dosage that may occur from the use of ordinary medicine droppers. This unreliable method is to be condemned, as it has been a significant factor in the inadequate administration of digitalis. Some physicians have presumed that a minim of the tincture of digitalis, as measured in a calibrated vial, corresponds to a drop as delivered by the average medicine dropper. That this method is unreliable can be proved by anyone by filling a calibrated vial to a given capacity in minims, using several droppers. Discrepancies of from five to fifteen drops will be observed. The position in which the dropper is held, vertically, obliquely, or horizontally, also results in a discrepancy. Graduated vials are readily available and one should be prescribed with the digitalis; it is easy to instruct the patient in its use.

Under certain conditions digitalis may be given satisfactorily by rectum. This method of administration is particularly applicable if nausea and vomiting are present from other causes. Essentially the same dosage used in oral methods may be used. In order to simplify this procedure, the total daily dose may be given at one time, with 20 to 25 c.c. of water added.

The intravenous and intramuscular injection of digitalis has already been discussed, and I wish to emphasize that the indications for this mode of administration occur only occasionally.

#### TOXIC EFFECTS

Every physician should understand the toxic effects of digitalis. Certain symptoms of overdosage are well known; namely, anorexia, nausea, vomiting, and diarrhea. The occurrence of coupled beats as toxic manifestations has also received con-

siderable emphasis, and likewise the occurrence of partial or complete heart block. Other toxic effects are not so well known and merit considerable emphasis, owing to the fact that they often occur independent of such well-known symptoms as nausea and vomiting.

Occasionally, during the administration of digitalis, paroxysms of tachycardia occur which have been known to terminate in death. The paroxysms have been identified as arising in the ventricles. The occurrence of these phenomena during the course of administration of digitalis in a case in which the patient was not hitherto subject to them, indicates a profoundly toxic effect of the drug.

The toxic effects of digitalis on the brain and certain nervous tissues are important to recognize, as the continued administration of the drug when toxic effects are present, often results fatally. Prominent among these are disturbances in vision. They consist of dimness of vision, inability to focus the eyes, difficulty in identifying objects, and the presence of scotoma, diplopia, and so forth. Yellow and green vision are striking, and are often alarming manifestations of intoxication with digitalis.

Toxic cerebral effects of digitalis are not as yet fully appreciated and are of the utmost importance owing to their seriousness. In older medical writings, allusions are found to the so-called cardiac psychoses, some instances of which were probably the result of intoxication with digitalis. The first symptoms usually are restlessness and increased nervous irritability; periods of disorientation regarding time and place soon follow. These manifestations are frequently supplanted by stupor, from which the patient does not recover. Visual disturbances may or may not be associated phenomena. Toxic cerebral symptoms may occur without the more usual signs of poisoning by digitalis. The onset of any of these symptoms clearly indicates immediate discontinuance of the drug, for the time at least, and the prompt clearance of the tissues; this may at times be possible by the daily intravenous administration of hypertonic glucose solution.

## TREATMENT OF NEPHRITIS

EDWIN G. BANNICK

---

WITHIN the past twenty-two years there have been distinct advances in the classification and treatment of nephritis. In 1914, Volhard and Fahr assembled the known clinical, laboratory, and pathologic data and reclassified the various types of nephritis. Since then there have been numerous other similar classifications subdividing the old acute nephritis, chronic parenchymatous nephritis, and chronic interstitial nephritis into smaller groups. There have been many arguments concerning the pathologic changes in the various forms. New terminology such as nephrosis has appeared. Much has been written about hypoproteinemia and a decrease in the osmotic pressure of the serum as important factors in the production of edema. Frequent reference has been made to hypercholesterolemia, inversion of the albumin-globulin ratio in the serum, and decreased basal metabolism. Many articles have dealt with various phases of hypertension. Numerous diuretics have been made available. All of these have resulted in increased knowledge of the pathologic changes, the prognosis, and the treatment of the different types of nephritis, but unfortunately they also have caused some confusion in the minds of many physicians, particularly those who are not specializing in this field, who may feel that the problem is too complicated for the average physician to handle, especially if he does not have ready access to numerous laboratory procedures. I am firmly convinced, however, that this is not correct. Undoubtedly, some special data are at times of distinct value in accurate diagnosis and prognosis, and yet from the practical standpoint most patients who have nephritis can be well treated by any physician who will avail himself of the measures at his disposal and who is familiar with the general principles underlying the present treatment of renal disease. I, therefore, will outline

these general principles and mention the therapeutic measures which I think should receive consideration.

The classification in the Tabulation is a practical clinical arrangement which I have found very useful in the treatment of nephritis.

## TABULATION

### CLINICAL CLASSIFICATION OF NEPHRITIS

#### I. Acute nephritis (old classification: also acute nephritis):

(A) Acute diffuse glomerular nephritis.

(B) Acute nephrosis.

1. Acute chemical nephrosis.

2. Acute toxic nephrosis.

#### II. Chronic nephritis:

(A) Chronic nephritis with edema (old classification: chronic parenchymatous nephritis):

1. With little or no retention of nitrogen:

a. Lipoid nephrosis.

b. Mixed nephrosis.

2. With retention of nitrogen (chronic glomerular nephritis).

(B) Chronic nephritis without edema but with retention of nitrogen (old classification: chronic interstitial nephritis):

1. Chronic glomerular nephritis.

2. Arteriosclerotic nephritis.

### ACUTE NEPHRITIS

It is essential to differentiate the two forms of acute nephritis referred to in the Tabulation. This is advisable both from the standpoint of treatment and prognosis, and it is not difficult to do in most instances.

**Acute Diffuse Glomerular Nephritis.**—This type of nephritis is characterized by hematuria, albuminuria, and usually by some edema, hypertension, or retention of nitrogen, or all of them. In other words, it is a diffuse disease and not one that is limited to the kidneys. The onset is usually abrupt and is often preceded by some demonstrable etiologic factor, such as acute tonsillitis or some type of streptococcus infection. It is true that in some instances edema, hypertension or even the evidence of retention of nitrogen may not be very striking but careful examination and observation should reveal the presence of one or more of them. This finding together with a significant

hematuria and albuminuria is sufficient to establish the diagnosis.

I shall consider treatment somewhat in the form of an outline in order to compare it with the treatment of the other forms of nephritis which are to be described.

*General Measures.*—The patient should be put to bed and kept warm. It is oftentimes advisable to use light flannel garments for this purpose. The length of time that the patient should be kept in bed is rather disputable, but in general the tendency has been to allow these patients to get up much too soon. The patient and the relative must be given to understand that this disease, if properly handled in the early stages, is curable in the majority of instances but that, if allowed to become chronic, it is incurable and ultimately fatal. It would, of course, be desirable to keep such a patient in bed and warm until no abnormalities could be noted in the urine, blood pressure, or renal function, but this is at times impractical and perhaps often unnecessary. The patient should, however, be kept in bed until the edema has disappeared, until the blood pressure is normal, until the free output of urine is established, until hematuria has subsided or markedly diminished, or until there is unmistakable evidence that the disease has changed into the chronic stage. When the patient is finally allowed to get up, precaution should be taken to see that he is kept warm and that his activities are increased very slowly and cautiously. I have seen numerous cases of acute nephritis in which the patients made a splendid temporary recovery but the disease became chronic because the patient engaged in active work, oftentimes heavy farm work which was associated with chilling and exposure. In the early stages it is advisable to keep the bowels open by the use of mild laxatives, but I have not been impressed with the value of any purging, and this has been the experience of numerous other physicians.

*Diet.*—In the cases of mild nephritis, little dietary restriction is necessary. The diet should be adequate in amount and variety with only a little reduction in the protein content; many physicians do not even advise the latter. If edema is present, intake of salt should be reduced. A normal amount of fluid should be allowed unless there is considerable edema, when some restriction of fluids is desirable. In cases of severe

acute nephritis the immediate objective of the diet should be to put the kidney at rest as much as possible. Volhard, in Germany, usually gives the patient nothing by mouth for from three to five days, and Ellis, of England, gives only a pint of orange juice daily for ten to fourteen days. I have not deemed it necessary to restrict the patient as much as this, but I agree with the general principle of food and fluid starvation in the early stages of severe nephritis. I have usually prescribed only small amounts of fruit or fruit juices by mouth for the first few days and then have gradually increased the diet, but the protein content is kept low (around 30 gm. daily), the salt is restricted, and the diet, of course, is kept free from condiments, extracts, and irritants of all kinds. After a couple of weeks the protein content and the caloric value of the diet should be increased until the patient is taking an adequate diet with only moderate restriction of protein and salt.

*Fluids.*—In cases of severe nephritis the ingestion of fluids should be markedly limited for the first few days for the same reason that the diet is restricted. After a few days, however, the fluids should be gradually increased, depending on the degree of oliguria and the amount of edema that are present. There has been a general tendency to give too much fluid in the early stages of this disease. I do not advise giving more than 2,500 c.c. of fluid during twenty-four hours, and this quantity should be given only later when the patient is excreting a considerable amount of urine and when there is no edema. It seems reasonable that if the patient is receiving 2,500 to 3,000 c.c. of fluid daily and is excreting only 200 to 300 c.c. of urine daily, without any excessive loss of fluid through the other channels, an unfavorable situation will result. Under these circumstances, I think the amount of fluid should be reduced again. I have seen numerous instances in which such a fluid imbalance has been allowed to persist for a considerable length of time without any demonstrable peripheral edema, and yet at necropsy the patient was found to be markedly water-logged. In case the oliguria persists, it is advisable to give some of the fluids intravenously in the form of hypertonic solutions. It is advisable to begin by using a 10 to 20 per cent solution of dextrose. If the oliguria is marked, 500 c.c. of a 20 per cent solution of dextrose should

be given intravenously. If it is not marked, 750 c.c. or even 1,000 c.c. of a 10 per cent solution of dextrose may be used instead. In some cases in which the condition is obstinate, sucrose has seemed to produce even better results, because the diuretic effect of the hypertonic solution of sucrose is maintained much longer than that of dextrose, inasmuch as sucrose is not utilized by the body as is dextrose, and must be largely excreted through the kidneys. The solution of sucrose must be carefully prepared, however, and in cases in which this has been done, I have not had any unsatisfactory experiences with it either in the way of toxic reaction or renal damage. If there is persistent oliguria and considerable retention of nitrogen, there is usually an associated acidosis, in which case it also is advisable to administer 300 to 500 c.c. of 5 per cent solution of bicarbonate of soda intravenously.

*Diuretics.*—Apart from the intravenous administration of the hypertonic solutions which have been mentioned, diuretics are for the most part not indicated. I do not believe that other diuretics are of much value unless there is considerable edema, and this is not true in the vast majority of cases in which the treatment is well managed. The field for diuretics is in cases in which there is edema and not in those in which there is acute oliguria. The administration of salyrgan, a compound of organic mercury, is distinctly contraindicated and would likely produce further damage if used, and I have noted little value from the acid-producing salts (ammonium nitrate, ammonium chloride, and calcium chloride) or from potassium nitrate, or the definitely alkaline diuretics, and if any of these are not very carefully administered, toxic symptoms will result in cases in which there is oliguria. The use of the xanthine diuretics in these cases also has resulted in considerable controversy. It has been argued that they are renal irritants and, therefore are likely to result in further damage to the kidneys. I have not been particularly impressed with this fact myself and as a result of this have used some of the xanthine diuretics in some instances of oliguria in acute glomerular nephritis, but I have not been much impressed with the benefits obtained. In some cases where there is considerable hypertension with evidence of myocardial insufficiency, administration of digitalis may produce much benefit.

*Special Symptoms.*—The special symptoms that require further consideration are anuria and convulsions. Anuria is fortunately rare, but when it occurs it presents a very serious and difficult therapeutic problem. Of course, it is advisable first to catheterize the patient to be sure that anuria actually exists. Then, it is advisable to administer some hypertonic solution intravenously, as previously mentioned, that is, 500 c.c. of a 20 per cent solution of dextrose, 350 c.c. of a 30 per cent solution of dextrose, or 400 to 500 c.c. of a 25 per cent solution of sucrose. It is often advisable to precede the intravenous injection of the fluid with a venesection and the withdrawal of 400 to 500 c.c. of blood. This is particularly true in cases in which there is acute hypertension. Intravenous administration of a 5 per cent solution of sodium bicarbonate is advisable if the anuria persists. Surgical decapsulation of one or both kidneys should, of course, receive serious consideration in the face of persistent anuria. However, the selection of suitable patients for this operation is very difficult. If one can be sure that he is dealing with an acutely swollen kidney, and if the conservative measures which have been outlined have failed to produce satisfactory results, and if the patient is steadily losing ground, this surgical procedure should be instituted before the patient's condition becomes hopeless. This procedure has unquestionably resulted in the recovery of patients who otherwise would certainly have died. It should be borne in mind, however, that many times, when the surgeon was about to perform such an operation and before it was done, spontaneous diuresis has occurred. In many other instances the patients have been poorly selected so that the kidney was not found to be acutely swollen and tense, and no benefit has resulted from the decapsulation. Diathermy and very light doses of roentgen rays over the kidneys have been recommended, but I have failed to see any significant benefit in the few cases in which I have tried these measures.

In my experience convulsions are not common during acute nephritis which affects adults. Several measures must be considered in the treatment of convulsions when they do occur. First of all, it is advisable to see that the patient is propped up in bed with his head well elevated. This is particularly true if considerable edema is present. Sedative drugs, such as

chloral hydrate or the barbiturates, are, of course, indicated. The latter drug is given subcutaneously or even intravenously in certain instances. Venesection followed by the intravenous injection of a hypertonic solution of dextrose is often beneficial. In these instances I prefer the intravenous administration of small amounts of a strongly hypertonic solution of dextrose, for example, 250 to 300 c.c. of a 25 or 30 per cent solution, after the withdrawal of 400 to 500 c.c. of blood. I have seen lumbar puncture with the withdrawal of some cerebrospinal fluid stop a series of convulsions in several instances, and peculiarly enough, it may do so even when the cerebrospinal fluid is under no demonstrable increased pressure. Magnesium sulfate administered intramuscularly has been used with benefit by some physicians, but I have not had occasion to use it. The dose recommended is 0.2 to 0.4 c.c. of a 25 per cent solution for every kilogram of body weight. This may be repeated in two to three hours if necessary.

*Removal of Foci of Infection.*—Lastly in the management of acute diffuse glomerular nephritis, the problem of removal of foci of infection must be considered. Definite foci of infection should be eradicated. In the past it has been the policy to postpone removal of the focus until the attack of nephritis was well under control and until the hematuria and albuminuria had markedly diminished, but more recently there has been a feeling among many physicians working in this field that early removal of significant foci is desirable. A few years ago I discussed this problem at some length with Professor Nonnenbruch, of Prague, who has had a large experience in the management of renal disease, and he was convinced that prompt removal of significant foci in such cases was not dangerous but distinctly advisable. At the clinic we have removed foci of infection somewhat earlier than formerly, and yet we still prefer to remove them after the acute process has largely subsided unless the focus shows a very active infection and the hematuria is profuse, in which case early removal of the focus is indicated. In cases of very mild nephritis in which there are no abnormal findings except albuminuria and hematuria, prompt removal of significant foci of infection frequently results in a rapid cure without the necessity of much

else in the way of treatment, but subsequent close rechecking of such cases is advisable.

**Acute Nephrosis.**—Two types of this form of nephritis can be distinguished according to the etiology, namely, acute chemical nephrosis and acute toxic nephrosis.

*Acute Chemical Nephrosis.*—The most frequent cause of this condition is ingestion of bichloride of mercury. Other poisons which can produce it are uranium salts, chromium salts, arsenic, tartrates, phenol, and fluorides. The clinical picture is that of azotemia and oliguria which may become an actual anuria. The small amount of urine may contain albumin, blood, and casts as a result of the tubular necrosis. Edema and hypertension are rare except as late phenomena in cases in which the condition is poorly managed or proves fatal.

The therapeutic indications are chiefly twofold: (1) the prompt removal of as much as possible of the poison from the gastro-intestinal tract and neutralization of the remainder by proper antidote when possible, and (2) the treatment of the acute anuria, which has been described in the treatment of anuria in the preceding pages. Of importance in the treatment of poisoning with bichloride of mercury is the announcement by Rosenthal of an effective antidote for this substance. The antidote is sodium formaldehyde sulfoxylate (a powerful reducing agent) which reduces the toxic preparations of mercury to the mercurous state and to metallic mercury. The patient's stomach should be washed promptly and 200 c.c. of a 5 per cent solution of this antidote should be left in the stomach. This may be followed by the intravenous injection of 10 gm. of this preparation in 100 to 200 c.c. of distilled water. This may be repeated if the condition is severe. This treatment is highly effective as late as two hours after the ingestion of the poison and should be tried even if a longer period has elapsed.

*Acute Toxic Nephrosis.*—Whereas acute chemical nephrosis is fortunately rare, acute toxic nephrosis is very common, in fact, this represents one of the most common clinical forms of acute nephrosis or nephritis which the physician is called on to treat. It occurs in the course of many severe types of toxemia, as peritonitis, jaundice, empyema, septicemia, toxic gangrene, intestinal obstruction, pneumonia, malaria. Clinic-

ally, this form of nephritis differs from acute diffuse glomerular nephritis chiefly in the absence of such extrarenal factors as hypertension and edema, although edema may occur later if excessive amounts of fluid and salt are allowed with persistent oliguria. Urinalysis also does not reveal the degree of albuminuria and hematuria commonly seen in cases of acute diffuse glomerular nephritis. In some instances a moderate albuminuria occurs, but hematuria is absent or slight. As in the cases of acute chemical nephrosis, the characteristic clinical findings are oliguria and retention of nitrogen. The severity of the symptoms varies greatly; there may be mild simple febrile albuminuria with good renal function or there may be fatal anuria and uremia. Pathologically, the renal changes also are not consistent. If the underlying etiologic factor can be corrected, the recovery is usually prompt and complete. Acute toxic nephrosis, therefore, may present an entirely different problem from that of acute diffuse glomerular nephritis and does not usually require the rigid management of the latter. The treatment otherwise is similar to that of acute oliguria in the more diffuse form of the disease with the exception that a more liberal fluid intake is advisable. This, however, as in the other group, depends on the degree and persistence of the oliguria. I think it is advisable to give 2,500 to 3,000 c.c. of fluid daily in such cases provided the output of urine increases proportionately, and if it does not, the intake of fluids must be gradually reduced so as to prevent the patient from becoming water-logged. During the period of oliguria it is advisable to restrict the intake of both salt and protein. Diuretics of the xanthine group are often of benefit in these cases. Of this group I prefer to administer theophylline-ethylenediamine (aminophyllin, euphyllin) in doses of 0.2 gm. three to five times daily. If the drug cannot be administered by mouth, it may be given subcutaneously or intravenously.

#### CHRONIC NEPHRITIS

Before taking up the various types of this condition, I would like to emphasize two broad general principles which govern its management. If the physician is thoroughly familiar with these principles, he should be able to prescribe in a

rational manner without necessity of a large amount of laboratory data. These broad general principles as applied to the treatment of chronic nephritis are as follows: (1) edema calls for the use of diuretics, rigid restriction of salt, some restriction of fluids, and of itself does not call for any restriction of protein; (2) retention of nitrogen of itself calls for restriction of protein, no restriction of salt, liberal administration of fluids, and no diuretics.

First, I wish to consider the *cases of chronic nephritis with edema*. This group for therapeutic reasons is divided into those with little or no retention of nitrogen and those with retention of nitrogen. The former includes those rare cases of chronic lipoid nephrosis in which the condition is handled in practically the same manner.

**Chronic Nephritis with Edema Having Little or No Retention of Nitrogen.**—The most progress in the treatment of chronic nephritis in recent years has been made in this group because of the knowledge of the rôle of the decrease in the serum protein in the production of edema and because of numerous suitable diuretics which have been developed. Although Bright himself, in his early writings, was aware of the decrease in the plasma proteins in these cases, for the most part patients who belong to this group have been badly managed for many years. Presenting themselves to the doctor with marked edema and marked albuminuria, the doctor was very likely to prescribe a diet rigidly restricted in protein because they had Bright's disease, and the doctor had been taught that patients who had Bright's disease should have very little protein. Epstein's contributions, based on Starling's earlier observation (1895-1896), opened up a new field of thought in the management of these patients. Starling showed that it is presumably the osmotic attraction of the plasma proteins for water that balances in the capillaries the hydraulic pressure tending to force the fluid out into the tissue spaces, and that when the protein osmotic pressure weakens, because of decrease in concentration of protein, undue amounts of fluid are likely to pass out into the tissues. Epstein (1917) made clinical application of Starling's experimental and theoretical work by observing a marked deficit in plasma protein in cases of chronic nephrosis in which there was noncardiac edema. These

observations have since been confirmed by many workers. He found further that the serum albumin was diminished chiefly and that there was, therefore, a tendency to inversion of the normal albumin-globulin ratio with still further decrease in the serum osmotic pressure. Govaerts (1924) showed that the albumin exerts four times as much osmotic pressure per gram as does the globulin. Epstein postulated that the decrease in the serum protein was attributable to loss of huge amounts of albumin through the kidney and, therefore, in place of a restricted protein diet which would further increase the serum protein deficiency, the patient should have a very high protein diet.

Time has shown that the hypoproteinemia is not entirely attributable to loss of albumin through the kidneys and that the value for the serum protein is not easily or uniformly elevated simply by the ingestion of an excess of protein. The ability of the patient to metabolize and utilize the protein given is, of course, a very important factor and experience has taught us that very high protein diets are unnecessary and may actually be harmful in some instances. On the other hand, since in these cases there is little tendency to retention of the end-products of protein metabolism and since the values for the serum protein are consistently low and there is considerable loss of albumin in the urine, the protein should not be restricted. The diet, therefore, should contain ample protein to insure a positive nitrogen balance with an additional supply available for storage. Approximately 100 gm. daily seems to be adequate for the average adult, and this amount is usually well tolerated by the patient. A rigid restriction of salt is also very important in controlling the edema.

The influence of a rigid restriction of salt on nephritic edema has been known for a long time, and further comment is unnecessary except to emphasize this fact and to point out that the food must be carefully prepared without the addition of any salt if the best results are to be obtained, and the butter must be free of salt. Fluid should be moderately but not rigidly restricted. Some physicians, notably Lashmet and Newburgh, at the University of Michigan, expressed the opinion that liberal amounts of fluid should be given and that if the salt is markedly restricted this will result in increased

elimination of salt and with it water. My experience has been that the edema is more easily controlled with moderate restriction of water in addition to rigid restriction of salt.

*Diuretics.*—Diuretics are usually indicated, in fact, this group of patients presents the chief field for the use of diuretics in nephritis, and numerous ones are available. At the clinic, we prefer the acid-producing salts (ammonium chloride and ammonium nitrate) or potassium nitrate and potassium chloride, which produce a mildly alkaline reaction. The nitrate salt in each group is the more effective diuretic. These salts will cause an increased elimination of salt and water in most instances. They are given by mouth in doses of from 8 to 12 gm. daily (ammonium nitrate usually is given in doses of 8 to 10 gm. daily, and potassium nitrate in doses of 10 to 12 gm. daily) and can be administered over a prolonged period with benefit and with safety if the patient is closely observed. Since the ammonium salts cause an increase of urea and a decrease in the alkali reserve, determinations of the blood urea and the carbon dioxide combining power of the plasma should be made periodically during their administration. Potassium nitrate is less likely to cause significant changes in the chemistry of the blood, and since it is a more efficient diuretic we are using it chiefly at the present time at the clinic. These drugs can be obtained in 0.5 gm. enteric-coated pills and if so administered do not as a rule cause nausea or vomiting.

Definitely alkaline diuretics have also been used successfully, particularly by English physicians, but the dosage in order to be effective must be large, and the potassium salts rather than the sodium salts are preferable because they produce better diuresis.

Bennett suggested the following:

Potassium bicarbonate	..	15 grains (1 gm.)
Potassium citrate		15 grains (1 gm.)
Water to make 1 ounce	(30 c.c.)	

An ounce of this to be taken every six hours, every four hours and every two hours, respectively, on successive days until the urine is fully alkaline.

Osman used considerably larger doses of a mixture of

potassium citrate, potassium bicarbonate, sodium citrate, and sodium bicarbonate in equal amounts. Such large doses of alkalis are often difficult to administer because of the tendency toward vomiting and diarrhea, and tetany constitutes one of the menaces of this treatment. Thus, it is interesting to note that diuresis may occur either following the use of large doses of alkalis or following the use of acid-forming salts such as I have mentioned, or following the administration of the very mildly alkaline potassium nitrate, and this fact should be kept in mind in managing obstinate nephritic edema. At the Clinic, we prefer ammonium nitrate or potassium nitrate because diuresis is more prompt, more striking and more constant, and the administration of the drugs is more simple and better tolerated by the patient. Urea is also used as a diuretic, but I believe that the ammonium salts described previously are much more efficient and may be used in any case in which the administration of urea is indicated. If there is evidence of complicating myocardial failure, the use of digitalis should be considered. In certain selected cases of chronic nephritis with edema and without nitrogen retention, the organic compound of mercury salyrgan has been used in conjunction with the acid-producing salts or potassium nitrate with good results, particularly in cases of chronic lipoid nephrosis, but this compound should be cautiously administered at all times, and if there is hematuria it should not be used. Much harm can result from the indiscriminate use of this potent diuretic drug whose chief field of usefulness is after all in the treatment of cardiac dropsy rather than in the treatment of nephritic edema. In obstinate nephritic edema without hematuria, it may prove to be very effective and probably without danger if properly administered. The initial dose should not exceed 0.5 c.c. intravenously, and if no untoward effects result from this the dose may be increased to 1 or 2 c.c. given not oftener than every four days and preferably at longer intervals. Other diuretic substances such as thyroid extract and the xanthine compounds should be kept in mind but have rarely been necessary nor very effective in my experience in this type of case.

Other measures, in addition to a liberal protein diet, have been advocated to aid in elevating the value for the plasma protein and the osmotic pressure of the serum. Blood trans-

elimination of salt and with it water. My experience has been that the edema is more easily controlled with moderate restriction of water in addition to rigid restriction of salt.

*Diuretics.*—Diuretics are usually indicated, in fact, this group of patients presents the chief field for the use of diuretics in nephritis, and numerous ones are available. At the clinic, we prefer the acid-producing salts (ammonium chloride and ammonium nitrate) or potassium nitrate and potassium chloride, which produce a mildly alkaline reaction. The nitrate salt in each group is the more effective diuretic. These salts will cause an increased elimination of salt and water in most instances. They are given by mouth in doses of from 8 to 12 gm. daily (ammonium nitrate usually is given in doses of 8 to 10 gm. daily, and potassium nitrate in doses of 10 to 12 gm. daily) and can be administered over a prolonged period with benefit and with safety if the patient is closely observed. Since the ammonium salts cause an increase of urea and a decrease in the alkali reserve, determinations of the blood urea and the carbon dioxide combining power of the plasma should be made periodically during their administration. Potassium nitrate is less likely to cause significant changes in the chemistry of the blood, and since it is a more efficient diuretic we are using it chiefly at the present time at the clinic. These drugs can be obtained in 0.5 gm. enteric-coated pills and if so administered do not as a rule cause nausea or vomiting.

Definitely alkaline diuretics have also been used successfully, particularly by English physicians, but the dosage in order to be effective must be large, and the potassium salts rather than the sodium salts are preferable because they produce better diuresis.

Bennett suggested the following:

Potassium bicarbonate	15 grains (1 gm.)
Potassium citrate	15 grains (1 gm.)
Water to make 1 ounce (30 c.c.)	

An ounce of this to be taken every six hours, every four hours and every two hours, respectively, on successive days until the urine is fully alkaline.

Osman used considerably larger doses of a mixture of

potassium citrate, potassium bicarbonate, sodium citrate, and sodium bicarbonate in equal amounts. Such large doses of alkalis are often difficult to administer because of the tendency toward vomiting and diarrhea, and tetany constitutes one of the menaces of this treatment. Thus, it is interesting to note that diuresis may occur either following the use of large doses of alkalis or following the use of acid-forming salts such as I have mentioned, or following the administration of the very mildly alkaline potassium nitrate, and this fact should be kept in mind in managing obstinate nephritic edema. At the Clinic, we prefer ammonium nitrate or potassium nitrate because diuresis is more prompt, more striking and more constant, and the administration of the drugs is more simple and better tolerated by the patient. Urea is also used as a diuretic, but I believe that the ammonium salts described previously are much more efficient and may be used in any case in which the administration of urea is indicated. If there is evidence of complicating myocardial failure, the use of digitalis should be considered. In certain selected cases of chronic nephritis with edema and without nitrogen retention, the organic compound of mercury salyrgan has been used in conjunction with the acid-producing salts or potassium nitrate with good results, particularly in cases of chronic lipoid nephrosis, but this compound should be cautiously administered at all times, and if there is hematuria it should not be used. Much harm can result from the indiscriminate use of this potent diuretic drug whose chief field of usefulness is after all in the treatment of cardiac dropsy rather than in the treatment of nephritic edema. In obstinate nephritic edema without hematuria, it may prove to be very effective and probably without danger if properly administered. The initial dose should not exceed 0.5 c.c. intravenously, and if no untoward effects result from this the dose may be increased to 1 or 2 c.c. given not oftener than every four days and preferably at longer intervals. Other diuretic substances such as thyroid extract and the xanthine compounds should be kept in mind but have rarely been necessary nor very effective in my experience in this type of case.

Other measures, in addition to a liberal protein diet, have been advocated to aid in elevating the value for the plasma protein and the osmotic pressure of the serum. Blood trans-

fusions are of undoubted value in doing this and would be used oftener for this purpose were it not for the fact that they are expensive and usually are not necessary. Intravenous injections of solutions of acacia have been used to increase the osmotic pressure of the serum. To be effective large doses must be given and may have to be repeated. The results have been variable and this method of treatment has not received general acceptance.

All definite foci of infection should be eradicated if the patient's condition and his ultimate life expectancy warrant it. This is particularly true in the cases of lipoid nephrosis in which the prognosis is good and in which recurrences of edema are common, but good judgment must be used because a severe exacerbation of the disease may be produced by the untimely removal of foci. A warm, dry, equable climate is preferable if economically possible, as it is in all cases of nephritis.

**Chronic Nephritis with Edema and Retention of Nitrogen.**—This group presents a hard therapeutic problem because of the difficulty of planning a diet to combat both the edema and the azotemia, and because few suitable diuretics are available. The *diet*, of course, should be as free of salt as possible, just as it should be in the cases of edema without retention of nitrogen, but the amount of protein in the diet should be moderately reduced. However, because of the edema and the decreased value for the plasma proteins and because of the albuminuria, it is not wise to restrict the proteins in the diet rigidly. Sufficient protein should be allowed to maintain a positive nitrogen balance. A diet containing from 50 to 60 gm. of protein is usually sufficient to do this. This may need to be altered somewhat as treatment continues, depending on whether azotemia becomes the prominent symptom, in which case further slight reduction in the amount of protein may be made, or whether edema becomes the prominent symptom, in which case a more liberal amount of protein may be allowed. A fairly liberal fluid intake should be allowed, at least until the azotemia has been reasonably well controlled. It is often advisable to administer some of the fluid (500 c.c.) intravenously in the form of 20 per cent solution of dextrose or a 25 per cent solution of sucrose, because of the diuretic properties of such hypertonic solutions.

Suitable *diuretics* are somewhat limited. The organic compound of mercury (salyrgan) is usually contraindicated because of the likelihood of causing further renal damage. Ammonium chloride and ammonium nitrate tend to produce further retention of nitrogen and acidosis, and, therefore, are usually not desirable. Potassium nitrate is somewhat safer and more effective, but it must also be used cautiously, in smaller doses, and over a shorter period than usual because of the danger of a toxic reaction from the retention of potassium. It should not be used at all if the value for the blood urea is as high as 100 mg. per 100 c.c. The same caution must be used in administering potassium citrate or potassium bicarbonate. The alkaline diuretics, sodium bicarbonate and sodium citrate, and the xanthine diuretics, particularly theophylline-ethylenediamine (aminophyllin, euphyllin) or theobromine calcium salicylate (theocalcin) may be tried. These have been referred to in the previous pages, but, as mentioned, they have not in my experience produced uniform effective diuresis. Blood transfusions may be of much benefit in treating the edema, the anemia, and the azotemia.

**Chronic Nephritis without Edema but with Retention of Nitrogen.**—As mentioned previously under the general principles in the treatment of chronic nephritis, the ingestion of protein should be restricted in this type of nephritis, salt should not be restricted, and a liberal fluid intake should be allowed. In such cases the nephritis is unfortunately frequently overlooked and a liberal amount of protein is allowed because the most prominent presenting symptom is often anemia, for which treatment is given. If such a patient is thoroughly examined, hypertension and low specific gravity of the urine with some degree of albuminuria or hematuria practically always will be noted, in which case the azotemia should be suspected and easily proved, and proper treatment instituted. It has been aptly said that the combination of anemia and hypertension should make the physician suspect, first of all, chronic nephritis. It is not advisable to reduce the daily intake of protein below 40 gm. Further restriction than this over a prolonged period is likely to result in utilization of the protein in the patient's tissues. If the patient understands

that the average normal diet contains approximately 70 to 90 gm. of protein, he can readily appreciate to what extent he should reduce the protein in his own diet, even if no actual dietary list is given to him. A normal amount of salt is allowed because there is no edema, and the value for the plasma chloride is usually reduced. A liberal fluid intake of from 2,500 to 3,000 c.c. daily is advisable unless there is associated threatening cardiac decompensation. The fluid may be given orally unless prevented by nausea or vomiting, in which case some of it may be given rectally, subcutaneously, or intravenously. If the last method is used, a physiologic solution of sodium chloride or a 5 per cent solution of dextrose is preferable and should be slowly administered so as not to cause cardiac embarrassment. Diuretics other than the fluids which have been mentioned are of little value and, with the exception of digitalis, are not indicated in cases in which associated cardiac decompensation is present. Blood transfusions may have a temporary beneficial effect on the anemia and the azotemia if the economic status justifies such therapy. The anemia is very resistant to treatment. I have tried iron, bone marrow extract, and liver extract without any significant beneficial results.

The hypertension of chronic nephritis demands no particular therapeutic consideration, and when renal insufficiency exists, attempts to lower the blood pressure are inadvisable. Fortunately, however, they are usually unsuccessful. Cardiac failure is always threatening in the late stages of the disease, and the cardiac load should be reduced as much as possible. Digitalis may be beneficial in bolstering up the heart before actual decompensation occurs.

## SIGNIFICANCE OF HEMATURIA

JOHN L. EMMETT

---

A TREMENDOUS amount of statistical data has been accumulated on the subject of hematuria. In fact, so much information on this subject is available that the presence of hematuria at once stipulates that certain probabilities exist with almost mathematical certainty. The statistics furnished by Lower, MacKenzie, Van Duzen, Kretschmer, and Debenham speak for themselves. Large masses of detailed figures are often soon forgotten and the average practicing physician finds it difficult to keep abreast of the current medical literature, let alone find time to go to a well-stocked medical library and delve into articles of the past. For this reason, an occasional brief résumé of such an important subject in the current journals is valuable.

Articles on the subject of hematuria usually begin with a scathing criticism of physicians who neglect to investigate every case of hematuria thoroughly. Almost every article ends with a plea to the profession to stop prescribing medication for hematuria, but instead to urge the patient to submit to a thorough urologic examination. Personally, I believe that an extremely large proportion of the medical profession is alert to this subject. Patients who have extensive advanced lesions of the genito-urinary tract occasionally have been treated with drugs for months or years, but if the true facts were known it would be found only too often that the patients probably had refused the advice of their physicians and had insisted that symptomatic treatment be given.

There is another very important phase of this subject that is frequently forgotten. The specialist in a large clinical center who sees a tremendous number of referred patients becomes so overly aware of certain disease conditions that he often criticizes

too severely the physician who occasionally misses a diagnosis. One must remember, for instance, that the general practitioner in a relatively small community who does not have ready access to a roentgenologic laboratory is not able to subject every patient who has gastric distress to a thorough roentgenologic study of the gastro-intestinal tract. The clinical acumen which he has gained from years of hard-earned experience should enable him to select the patients who should be sent for complete investigation. It is only in this way that the medical expense of the community can be kept within reason.

The problem of the practitioner therefore is to follow a course that will supply the highest type of scientific diagnosis to his clientele with the minimum of diagnostic errors as well as the minimum of unnecessary expensive special examinations. With this truism in mind, I shall consider hematuria from the *practical standpoint of the general practitioner*.

The term "hematuria" means blood in the urine; the blood may be seen either grossly with the naked eye or with the microscope. Should the microscopic appearance of blood in the urine be regarded with the same suspicion as gross hematuria or may it be disregarded? Is the physician requiring too much of his patient if he insists on a complete urologic examination when only a few erythrocytes have been found in the urine? A practical answer to these questions is that, when the microscopic appearance of blood in the urine is not associated with symptoms, repeated urinalysis should be made. If the erythrocytes persist in the urine or if they appear intermittently, the condition should be regarded with the same suspicion as gross hematuria. It must of course be remembered that it is necessary to obtain a catheterized specimen of urine if the patient is a woman, as erythrocytes in a voided specimen are of no diagnostic significance. The rule may be laid down, therefore, that if microscopic hematuria persists on several subsequent examinations or if it is found intermittently, it must be regarded with the same suspicion as gross hematuria.

In the remainder of the paper I shall speak of hematuria as indicating gross hematuria or persistent or intermittent microscopic hematuria. It is not the purpose of this paper to present imposing complete lists of the conditions, both medical and surgical, in and outside of the genito-urinary tract, that

may be responsible for the hematuria, but rather to acquaint the physician with the serious possibilities involved and suggest a rational and practical plan of procedure.

The problem involved in hematuria becomes apparent when one analyzes the 798 consecutive cases of hematuria reviewed by Lower. In almost a third (32 per cent) of these cases the hematuria was the result of new growths in the genito-urinary tract; in 11 per cent of the cases it was attributable to tuberculosis, and in 16 per cent of the cases it was the result of a calculus. In other words in 59 per cent of the cases the patients were suffering from a most serious condition that demanded early diagnosis if any hope of cure were to be offered. Armed with the facts, therefore, that the chances are about six in ten that one of the preceding conditions might be present, it should not be difficult for the physician to convince patients who are suffering from hematuria that a complete urologic examination is imperative.

There are a few general statements that are easily remembered concerning hematuria. Hematuria is much more common among men than it is among women. The most common cause of hematuria among women is inflammation of the genito-urinary tract, while the most common causes of hematuria among men, in the order of their frequency, are vesical tumors and benign prostatic hypertrophy. Debenham made an interesting investigation of 742 consecutive cases of hematuria. For the sake of analysis these cases may be divided into two groups. Group 1 will be used to include the 510 cases in which the patients were men and group 2 will be used to include the 232 cases in which the patients were women. Inflammation of the genito-urinary tract was the cause of the hematuria in 16 per cent of the cases in group 1 and in 46.5 per cent of the cases in group 2. It is not generally realized that benign prostatic hypertrophy is a much more common cause of hematuria among men than is carcinoma of the prostate gland. In 10 per cent of the cases in group 1 the hematuria was the result of benign hyperplasia of the prostate gland and in 3 per cent of the cases in this group the hematuria was attributable to carcinoma of the prostate gland. In 130 of the cases in group 1, the patients were more than sixty years of age. In 84 per cent of these 130 cases, the hematuria was attributable to carci-

noma of the bladder or prostate gland, benign prostatic hyperplasia, or stricture of the urethra.

A note of warning should be sounded concerning the attempt to determine the source of the hematuria by noting the time of appearance of the blood in relation to the act of micturition. If blood appears at the urethral meatus only between micturitions, the probability is that the source of the bleeding is anterior to the compressor urethrae muscle. However, the fact that the blood is initial, terminal, or completely mixed with the urine should not lead the physician to prognosticate its source. One frequently is led completely astray in this manner. Another point of importance, concerning which the physician must constantly be on the alert, is regarding the women who come to him complaining of irregular menstrual bleeding. Close questioning of such patients will occasionally reveal that their real trouble is hematuria. A carefully taken history in such cases will often avoid serious delay in diagnosis.

As a rule, cases of hematuria may be classified into three groups, according to the etiology. The first group includes cases in which the hematuria is a complication of some systemic disease, such as hemophilia, polycythemia vera, purpura hæmorrhagica (and symptomatic purpura), Hodgkin's disease, scurvy, paroxysmal hematuria, hypertension, various types of nephritis, including the acute nephritis which follows acute infective diseases such as scarlet fever, tonsillitis, and measles. Cases in which hematuria is caused by administration of drugs such as cantharides, turpentine, methenamine, and sodium salicylate, or by the ingestion of foods which are rich in oxalates also belong in this group. Group 2 includes cases in which the hematuria is the result of diseases of organs adjacent to the urinary tract. In these cases, of course, the possibilities are bizarre and unlimited and the condition may be caused by such diseases as carcinoma of adjacent structures, hernia with incarceration of the bladder, and pelvic inflammatory disease. Group 3 consists of cases in which the hematuria is caused by intrinsic lesions of the genito-urinary tract.

A good insight into the average incidence of these various conditions may be obtained by an analysis of the 860 cases of hematuria reviewed by Kretschmer. The causative lesion in these cases is shown in the Tabulation. It is of interest to

note that in 235, or 76.5 per cent, of the 307 cases in which the hematuria was attributable to lesions of the bladder the exciting cause was either carcinoma or papilloma.

The practical approach to the problem of diagnosis is not as formidable as this complete array of possible sources of hematuria would suggest. In fact, the problem may be approached as swiftly and as orderly as a chemical problem in qualitative analysis. For instance, it may be noted in the Tabulation that in 824, or practically 96 per cent of the 860 cases, the hematuria was the result of lesions within the genito-urinary tract, while in nine of the remaining thirty-six cases the hematuria was the result of systemic disease; in twenty-seven cases the cause of the hematuria was not diagnosed. These twenty-seven cases no doubt belong to group 1 or group 2, or were cases of essential hematuria.

The first step one should take, therefore, in all cases of hematuria is to make a complete urologic examination, which should establish the diagnosis in at least 95 per cent of cases. This should be done in spite of the fact that associated conditions such as hypertension or questionable chronic nephritis might possibly be causative agents. The burden of proof rests on the physician, who should make certain that there is not an intrinsic lesion of the genito-urinary tract. With modern urologic methods this is usually easy to do.

After this procedure there will remain only approximately 5 per cent of cases in which the physician will need to look further for the source of the hematuria. It is hardly within the province of the urologist to advise methods of procedure in the latter group of cases. Excellent articles have been written on the diagnosis of these medical conditions and almost every physician is acquainted with this phase of the problem. A word might be said here about the term "essential hematuria." This term has been used to denote those cases in which every effort that has been expended to establish a diagnosis as to the source of the bleeding has been unavailing. Of course this term, like the term "rheumatism," smacks of ignorance. In some of these cases the hematuria no doubt is the result of early lesions of the upper part of the urinary tract that are too small to be demonstrated by retrograde pyelograms or intravenous urography. However, there are cases in which

## TABULATION

## CAUSES OF HEMATURIA IN 860 CASES REVIEWED BY KRETSCHMER

<i>Lesions of the kidney</i>	<i>Cases</i>

patients suffer from intermittent hematuria for years without any impairment of their general health. No cause for the bleeding can be found in these cases. Bumpus reviewed 155 cases of "essential hematuria" five to twenty years after the diagnosis had been made at the Clinic and found that definite renal disease developed in only six of these cases. Calculi developed in three of these cases and in the remaining three cases nephrectomy was performed for unknown reasons. His conclusion was that there are many cases in which kidneys bleed without any demonstrable pathologic change and he expressed the opinion that the term "renal epistaxis" probably described this condition more accurately than any other term. The study of Wilbur and Priestley also substantiates this view. The value of a prompt and early diagnosis is enormous to the patient who is suffering from hematuria. For instance, in

the group of cases in which malignancy of the genito-urinary tract is found (which comprises almost a third of all the cases of hematuria), early diagnosis constitutes the only chance of cure. Braasch and Griffin, and Hand and Broders have emphasized the encouraging results of nephrectomy in the early treatment of malignant tumors of the kidney and ureter by reporting a number of five-year cures. Small early lesions of the bladder are often very satisfactorily cared for, whereas those that have been neglected and have grown to large proportions are absolutely hopeless. It is a regrettable fact, that as noted by Kretschmer, the average length of time, between the first attack of hematuria and the urologic investigation was two and a third years. The Committee on Carcinoma Registry of the American Urological Association found that in 46.45 per cent of cases of carcinoma of the bladder the disease had not been diagnosed one year after the first appearance of the hematuria. It is necessary to strive for earlier diagnosis. In malignant disease and in renal tuberculosis the only hope of cure lies in the early recognition of the condition when there is a possibility that the lesion may still be unilateral and before too much damage has occurred in the bladder. As far as calculous disease is concerned, many kidneys have been completely and painlessly destroyed when they could have been saved by early removal of the obstructing calculus when hematuria was first noted.

Having laid down the dictum, therefore, that every patient suffering from hematuria should be subjected immediately to a complete urologic examination, the economic problem again arises as to the proportion of a community that must be submitted to such inconvenience and expense. Van Duzen, in a review of 21,000 consecutive patients seen in an average clinical practice, found that 500, or only 2.38 per cent presented microscopic or gross evidence of blood in the urine. Eliminating those cases in which the hematuria was probably an accidental finding in the course of microscopic examination and could not be found on repeated examinations, one might estimate that between 1.5 and 2 per cent of patients seen in a general practice will require complete urologic examination because of hematuria. Certainly, this figure is minimal and presents no economic difficulties.

A serious duty then falls on the family physician, who should not only recognize this pertinent problem but should instruct his patients concerning the serious danger of neglecting a complete investigation in every case of hematuria. He will further aid his patients by refusing to prescribe drugs of any type for this condition. Few patients who are made acquainted with the general statistics which have been outlined will fail to heed his warning.

## URINARY INFECTIONS

EDWARD N. COOK

---

I HAVE been interested in the visual examination of the urine because of the numerous questions that have been asked me at various times regarding the technic of examination of the urine and also because of the great importance we have learned to attach to such an examination. It is surprising to find how many physicians have almost forgotten the first laboratory test they ever learned. The importance of the bacteriology of the urine has been stressed repeatedly, perhaps more so in the last five or six years than previously. It is definitely of value to the physician and to the patient to know whether or not a coccus or a bacillus is the causative organism in an existing urinary tract infection or whether no organism is present.

When a patient comes to the office the first laboratory procedure should be visual examination of the urine. If the patient is a male, after the glans penis and prepuce have been cleansed with soap and water and alcohol, the patient is asked to void 1 or 2 ounces into a first glass and the remainder into a second glass. In the female only a catheterized specimen is examined, because a voided specimen contains vaginal and cervical secretions which frequently obscure the true picture. If the first glass of urine is cloudy or hazy and the second is clear, it indicates that an anterior urethritis is present with or without involvement of the prostate gland. If the first glass of urine is shreddy and the second clear, chronic urethritis and infection of low grade are present in the prostate gland. If both glasses of urine are cloudy or hazy any of a group of conditions may be present; anteroposterior urethritis, prostatitis, cystitis, pyelonephritis, bacteriuria or phosphaturia. The last can be quickly determined by taking a small sample of

the urine and adding to it a few cubic centimeters of acetic acid. If the cloudiness is caused by the presence of these phosphates it will disappear rapidly. If the first glass of urine is clear, pyuria or bacteriuria is not ruled out because urine often may contain 20 or 30 cells to the high power field and yet appear clear on gross examination.

After the urine in the two glasses has been examined, a sample is taken from the second glass, and is centrifuged for five minutes. The supernatant fluid is drawn off and a drop of the sediment is examined on a clean glass slide to determine the amount of pus, and whether or not erythrocytes, crystalline elements or epithelial débris are present. The importance of the presence of epithelial débris has been demonstrated because in certain cases in which burning and frequency have continued after treatment, examination of the urine has revealed nothing more than a large quantity of old epithelial cells. They have been produced by chemical irritation of irritations. A smear is then made by spreading a drop of urine over the slide and staining with the simple Gram stain. Many modifications of this stain may be employed. Methyl violet may be substituted for gentian violet. Some of the organisms which are commonly found when the urine is examined by this method are: of the bacillary group, *Escherichia coli*, *Aerobacter aerogenes*, *Pseudomonas*, *Proteus*, and so forth; of the cocci, *Streptococcus faecalis* and a green-producing streptococcus are the most common, and organisms of the genus *Micrococcus* and the hemolytic streptococci are less often found. This grouping of the organisms can be identified by the Gram stain. Whether or not the organisms fall into the group of bacilli or cocci is of primary interest for on this will depend the method of treatment.

I would like to consider briefly the various methods of treatment. So far as the urinary antiseptics go, methenamine is, no doubt, the best urinary antiseptic to be administered by mouth. In a test tube the action of this drug depends on an existing pH of 5.5 or less. Ammonium chloride or ammonium nitrate may be employed to increase the acidity of the urine. Methylene blue is of particular value in cases of prostatism. The results with pyridium, hexylresorcinol, and serenium, have not been satisfactory. Potassium permanganate probably is

one of the best solutions to be employed for lavage of the bladder. In cases in which acidification of the urine is necessary, acetic acid, 1:3,000, is helpful. Silver nitrate and mercurochrome have their place in the treatment of infections of the urinary tract. A mild silver protein (argyrol) is of great help in cases of coccal cystitis. Silver nitrate is of value in the treatment of ulcerative cystitis; a 10 per cent solution is first employed and it is increased to 40 per cent. Intravenous injection of neoarsphenamine may be of aid in cases of coccal infections. Usually two or three injections are sufficient. The mode of action never has been definitely proved, but in 65 per cent of cases the organism will be eradicated. Strangely enough, the size of the dose apparently does not make a great deal of difference. At the clinic, 0.45 gm. was administered at first; this amount was reduced to 0.4 gm. and to 0.3 gm. and the results remained the same. Cocci do not grow well in the ordinary media and most of the fancier media. They must be identified by stain and not by culture. Gratifying results have been obtained when mercurochrome was employed, particularly in cases of fulminating pyelonephritis due to a bacillus. Five cubic centimeters of a 1 per cent solution in 500 c.c. of physiologic saline solution has produced seemingly miraculous results and the possibility of distressing colon complications is eliminated if such a mild solution is administered. Methenamine administered with physiologic saline solution has often proved of value.

It is practically impossible to reach a point that is bactericidal by acidification of the urine with drugs. Bacteriostasis may be produced and the patient will be relieved of symptoms by the drug alone. However, in only a few instances has the urine become sterile by the use of an acidulator. The ketogenic diet is still a very useful method in cases of bacillary infection of the urinary tract.

More recently the use of mandelic acid as suggested by Rosenheim has been of great value in the bacillary infections. It is given in a 10 per cent solution and the usual dosage is 2 tablespoonfuls (1 ounce) before meals and at bedtime. The pH of the urine must be adequate (below 5.4) and the fluid intake limited to 1,000 c.c. daily if good results are to be expected.

In summary, the Gram stain will give information as to the causative organism. If it is a bacillus, acidification of the urine by means of ammonium nitrate or the ketogenic diet is perhaps the most effective treatment.

Whenever cocci are found in the urine it is particularly important to eradicate all foci of infection. If infected tonsils or teeth are removed the results are remarkable. I do not believe good results will be obtained in the treatment of coccal infections of the urinary tract as long as any focus of infection remains. The teeth, tonsils, prostate gland in men and cervix uteri in women should be examined.

A third group of cases falls under the category of infections of the urinary tract because the patients respond to treatment for infections. We were taught that sterile pyuria means tuberculosis. During the last year and a half I have been impressed by the number of patients who have come to the Clinic with a diagnosis of tuberculosis which we have not been able to confirm by inoculation of guinea-pigs or by repeated examination of the urine. If foci of infection are removed and the ketogenic diet is administered, the patients do not have further symptoms. I believe the condition is caused by infection because of the response to treatment. The etiology certainly is vague at the present time. Possibly there is a focus of infection somewhere else in the body liberating toxins in the blood stream which may produce a toxic reaction in the urinary tract. The condition may be caused by coccal infection in the cortex of the kidney, with secondary infection in the pelvis of the kidney. Possibly it may be caused by a filtrable virus. Within the last few months a young man came to the Clinic with a diagnosis of renal tuberculosis. Pus was obtained from both kidneys and the bladder was markedly infected. Examination of the urine revealed pus, grade 4. Repeated examination of stains did not reveal *Mycobacterium tuberculosis*. Guinea-pigs which were inoculated with material from the kidneys and bladder did not give evidence of tuberculosis. Treatment in this case consisted of intravenous injection of neoarsphenamine, and tonsillectomy was performed. Six weeks later the urine was crystal clear and the patient did not have any symptoms. Six weeks after he had returned to

his home he had gained 16 pounds (7.3 kg.), and examination gave negative results.

A young girl came to the Clinic because of infection of the bladder. Examination for the gonococcus and *Mycobacterium tuberculosis* gave negative results. Treatment for urethritis was instituted. Two weeks after treatment was discontinued recurrence took place and treatment was again instituted. Four or five days after treatment was discontinued, recurrence again took place. Infected teeth and tonsils were not present. A vaginal discharge had begun just two days before the flare-up in the bladder. Treatment of the eroded cervix was begun and she has been entirely free from symptoms.

The three large groups in which infections occur are cases in which bacillus infection is present, cases in which coccal organisms are present, and cases in which no organism is demonstrable, which are not caused by tuberculosis. This simple method of examining the urine by Gram stain may be most helpful to the physician. It is carried out routinely on every patient who comes to the Section on Urology. We do not wait for the laboratory report but make the examination ourselves when the urine is fresh.

Visiting physician: Do you use the ketogenic diet in cases of acute infections of the kidney? Dr. Cook: No, we do not. The diet is a much more successful means of treatment if it is administered to patients who are up and around than if the patient is confined to bed. Exercise is of definite use in enhancing the value of the diet and producing a greater degree of ketosis.

Visiting physician: Would you include the lower rectum as one of the significant points of foci of infection for cocci? I have seen several cases in which I have wondered if infection of the urinary tract has not been associated with infection of the anal crypts. Dr. Cook: Occasionally such cases will be encountered, but I believe they are rare.

Visiting physician: Do you think that *Bacillus coli* infections are more common in the female than in the male? Dr. Cook: They certainly are more common in female children. In adults they occur equally among men and women.

Visiting physician: Have you used nitrohydrochloric acid?

Dr. Cook: We have found that urine can be acidified with nitrohydrochloric acid and ammonium chloride, but in cases in which acidification cannot be obtained with ammonium chloride the urine will not be acidified with nitrohydrochloric acid.

Visiting physician: Do you limit the amount of fluids in cases of infected urine? Dr. Cook: If the ketogenic diet is employed fluid is limited to six glasses each day. This is important because only a certain amount of ketone bodies will be formed as a result of the diet; if that concentration is lessened by excess of fluid, the desired result is not obtained.

Visiting physician: Is treatment instituted in cases of chronic urinary infections associated with peptic ulcer? Dr. Cook: If the ulcer symptoms are not too pronounced, treatment for the urinary infection is instituted. In one case the symptoms of the ulcer were increased. In six or eight cases a bland ketogenic diet was administered and treatment was completed. I think it is an individual proposition.

Visiting physician: Is ammonium nitrate preferred to ammonium chloride? Dr. Cook: I prefer ammonium nitrate because I do not believe it is as irritating to the gastro-intestinal tract.

Visiting physician: Do you use acriflavine? Dr. Cook: It is used for lavage of the bladder, for instillation and for urethral infections. A solution of 1:3,000 or 1:4,000 of acriflavine is used.

## TREATMENT OF PERSISTENT PYELITIS OF CHILDREN

HENRY F. HELMHOLZ

---

PYELITIS as seen in the child is usually a self-limited disease. The tendency to a cure is very evident even in cases in which the course is severe and acute. An illustration of this type of case is the following:

An infant was taken with a fever of 105° F. Physical examination revealed that the throat was intensely red, and that albumin grade 1, pus grade 4, and innumerable *Salmonella* organisms were present in the urine. Fluids were forced. The child was given sodium citrate and sodium bicarbonate, 0.3 gm. of each, four times a day for five days. In a culture made at this time were 400 colonies of *Salmonella* to 0.5 c.c. of urine. A week later there was still pus grade 1 in the urine. A month later the urine was sterile and free from pus.

This case illustrates the importance of careful bacteriologic studies. The type of the infecting organism as well as the number of organisms in a definite amount of urine should be determined. This amount I have taken as 0.5 c.c. When, after one week, only 400 organisms per 0.5 c.c. were found in the urine, it was evident that the patient was overcoming the infection successfully; therefore, further treatment was not given. Otherwise the cure in this case might have been credited to the particular type of treatment employed. Probably a considerable number of infections of the urinary tract run such a course. The infections that persist fall into two definite groups, one in which no evidence of stasis can be elicited on careful urologic examination, and the other in which stasis exists somewhere in the urinary passages. It was thought at one time that the severity of the acute stage had something to do with the persistence of the infection and that the type of organism might be a deciding factor in persistence

isolated from the same individual a varied series of organisms; namely, *Escherichia coli*, *Aerobacter aerogenes*, and *Pseudomonas*. Another common sequence is an infection with *Escherichia coli* which gradually will clear up and leave behind an unmixed infection with *Streptococcus faecalis* which, on continued treatment, disappears. The *Proteus ammoniæ* infections are extremely difficult to treat because of the tendency of the organism to split urea and produce a strongly ammoniacal urine. Experiments performed in vitro reveal that of the common organisms causing urinary infection, the *Proteus ammoniæ* is killed most readily by acidity alone. If the urine can be kept at a pH of 4.8 to 5.0, a urinary antiseptic is not necessary to kill the *Proteus ammoniæ*.

The more the various organisms are studied, and the more that is discovered concerning the bactericidal ranges wherein they are affected, the nearer can physicians come to the most effective therapy.

When stasis in the urinary tract is suspected because of chronic pyuria or bacilluria, difficulty of urination, colic, tumor, or hematuria, the following procedures should be carried out: blood urea, phenolsulphonphthalein output and residual urine should be determined and roentgenograms should be made of the kidneys, ureters and bladder. Then a cystogram should be made. Following this an excretory urogram should be taken. The next step is cystoscopic examination and ureteral catheterization for a culture and differential function, and lastly a retrograde pyelogram. The last part of the program must be carried out by a competent urologist.

In the presence of stasis, the choice of treatment depends on the findings and on the functional capacity of the kidneys. If one kidney is functionless and the other is functioning normally, operation is indicated. If a kidney continues to retain from 15 to 30 per cent of its function and there is a possibility of correcting the obstruction, every effort should be made, first, to eliminate or reduce to a minimum the infection before attempting to restore normal drainage. When this is accomplished hope for partial return of function is justified.

A greater difficulty arises when the lesion is bilateral, and as a result of stasis there has been gradual wearing away of renal function and thus an increase in the blood urea to 50

mg. per cent or more. This condition necessitates a very careful study of the surgical possibilities, if the reduced function is attributable to stasis, or, as is more frequently the case, if it is the result of stasis and infection. If stasis is present, every effort should be made to correct it first because, with impaired function, the urinary antisepsis does not function well, and partial return of function after operation may make its use more successful.

Let me consider, first, a patient who had chronic pyelitis, but whose renal function and urinary tract were normal. The child had had the infection for a number of years, and had had recurring attacks of fever with pyuria. The infecting organism never had been identified and a cure never had been bacteriologically determined. The treatment in a group of cases of this kind can be successfully carried out with methenamine, beta-oxybutyric acid (ketogenic diet) or with mandelic acid acting in an acid medium. Before the ketogenic diet came into use, I was able to show in a large series of cases, in which in some instances the pyelitis had persisted for from three to six years, that the condition could be cleared up rapidly with the use of methenamine and ammonium chloride. The essential feature of the treatment, and one which very frequently is overlooked, is the time that is required for the splitting of the formaldehyde from the methenamine. Methenamine is not bactericidal and is excreted unchanged by the kidney. When it enters the acid urine, formaldehyde immediately begins to split off, and if the  $pH$  of the urine is sufficiently low and sufficient time is allowed to elapse, a bactericidal concentration of formaldehyde will be produced. In studies which I carried out some years ago, I was able to show that bactericidal action was not likely to take place within the limits set by urination unless the  $pH$  of the urine was 5.5 or less.

In order to have a successful reaction with methenamine, a sufficient amount of ammonium chloride must be administered to have the  $pH$  of the urine as low as 5.5 or less. This can usually be done by giving from 0.5 to 1 gm. of ammonium chloride four times a day. When the before mentioned  $pH$  has been reached, as determined by chlorphenol red paper or nitrozone paper (Squibb), it is advisable to start

with the administration of methenamine. The dose is from 0.15 to 0.2 gm. four times a day for infants and from 0.3 to 0.5 gm. for children aged four to five years, and from 0.75 to 1 gm. for children from six to fifteen years of age. After forty-eight hours a culture of the urine is made, and the dosage is continued unless there is evidence of irritation, such as frequency or hematuria. If after another twenty-four hours the culture proves to be sterile, the medication is continued for another two or three days. At the end of this time a culture is again taken to make sure that sterility persists. The medication is then stopped, and after an interval of three or four days another culture is taken. If this is also sterile, the infection has been eliminated.

If after forty-eight hours of treatment, with a urinary pH of 5.5 or less, the urine is still full of bacteria, the dosage of methenamine is increased by 0.25 gm. per dose, and after an interval of twenty-four hours has elapsed, another culture is taken. If bacteria are found again, a similar increase in the dosage is made and this is continued until either a sterile urine is obtained, or evidence of irritation, such as frequency, pain, or hematuria, manifests itself. To attempt treatment without the control by culture is pure guesswork, because the urine may become sterile in twenty-four hours or may not become sterile in two weeks. Sterility can be ascertained only by culture. Treatment with methenamine, if the necessary conditions of time and acidity are observed, can produce a cure in from forty-eight to seventy-two hours.

In the past I have tried this treatment repeatedly for patients with good renal function who had stasis in the urinary passages, but with very infrequent success. Eventually it was concluded that in cases in which this treatment was employed without success, the presence of some anomaly of the urinary tract, which was responsible for obstruction should be suspected. The treatment thus came to be used as a therapeutic test for obstruction. In order to determine beyond doubt the presence of obstruction, cystoscopic examination was necessary but because this was considered a rather formidable procedure in examination of children, it was postponed as much as possible. With better methods of examination of the urinary tract, particularly with the development of excretory

urography, the recognition of obstruction and consequent stasis was greatly simplified. Consequently the practice of prolonged treatment with ammonium chloride and methenamine, as a therapeutic test, was less frequently used.

In contrast to the results of treatment with ammonium chloride and methenamine, treatment with either the ketogenic diet or mandelic acid, even in the presence of urinary obstruction was successful in a larger percentage of cases in which renal function was normal. However, the wisdom of not neglecting to try treatment with ammonium chloride and methenamine was illustrated in a recent experience. A patient was relieved of obstruction of the vesical neck, and the persisting infection with *Streptococcus faecalis* was treated with mandelic acid, but this treatment was not successful. Later nonspecific neoarsphenamine therapy was tried but this was also unsuccessful. Finally, the infection was cleared up by a short period of treatment with methenamine and ammonium chloride. The latter treatment consisted of 0.5 gm. of ammonium chloride and 0.3 gm. of methenamine given four times a day.

The ketogenic diet has been fully explained in numerous papers so that at this time it does not seem necessary to do more than call attention to some salient features of the treatment. Two conditions must be fulfilled in order to obtain a bactericidal urine: (1) the urine must have a  $pH$  of 5.5 or below, and (2) the concentration of oxybutyric acid in the urine must be 0.5 per cent or above. Presence of both of these values can be easily determined. Chlorophenol red paper, and nitrozone paper (Squibb) indicate the proper  $pH$ , whereas the proper concentration of beta-oxybutyric acid is usually indicated by the deep mahogany-red color obtained when 10 per cent ferric chloride and an equal amount of urine are combined. The  $pH$  of the urine has a tendency to rise rapidly after four or five days, and it may be necessary to give ammonium chloride to keep it below 5.5. The ketosis also may become less intense as the body accustoms itself to the high fat diet. The more rapidly the patient can be put into a state of ketosis, the more marked will be the ketosis, so that only two or three days should be allowed to pass before the maximal ketogenic-antiketogenic ratio is instituted. The ketogenic-

antiketogenic ratio of 4:1 usually produces a strongly bactericidal urine. A 1 per cent beta-oxybutyric acid solution is strongly bactericidal at a  $pH$  of 5.5. Concentrations as high as 2.5 per cent have been found. With beta-oxybutyric acid in the latter concentration, and at a  $pH$  of 5.5, probably the urine is the most strongly bactericidal that can be obtained by any means without danger of injuring the urinary tract. Space does not permit me to go into the details of the diet, but experience has proved that only with the help of a trained dietitian is the treatment likely to be successful.

Very much easier to administer and simpler to control is mandelic acid. This organic acid acts in a manner very similar to that of beta-oxybutyric acid. In practically the same  $pH$  range and the same concentrations, mandelic acid acts bactericidally. It is given as ammonium mandelate. If any further decrease in  $pH$  is necessary, ammonium nitrate can be given, or an acid ash diet instituted. Flavored with sarsaparilla it is very well disguised and is readily taken by children, and when diluted with charged water, the product is a very good imitation of root beer.

The bactericidal action of mandelic acid varies inversely as the  $pH$  of the urine and directly as the concentration of the acid. At a  $pH$  of 5, 0.25 per cent of the acid acts bactericidally; at a  $pH$  of 5.3, 0.5 per cent, and at a  $pH$  of 5.5, 1 per cent will act similarly. There is no difficulty in determining the  $pH$  of the urine by means of nitrozone paper or chlorophenol red paper. At present there is no method of determination of mandelic acid except the gravimetric method. It is essential, therefore, to determine the  $pH$  of the urine daily, and to make sure that the urine is in the necessary range below 5.5, because it is not likely that the concentration of the acid will be higher than 1 per cent. If the  $pH$  of the urine on a particular dosage of ammonium mandelate does not drop below 5.5, it is better to add ammonium chloride or ammonium nitrate instead of further increasing the dose of ammonium mandelate. If, on the other hand, the  $pH$  range is right, and after several days' administration the urine does not show signs of reduced bacterial content, it becomes necessary to increase the dose of mandelic acid. Figuring complete excretion in the

urine the approximate concentration in the urine can be calculated from the twenty-hour specimen.

The dose for adults is about 12 gm. per day, 3 gm. given at intervals of six hours. The dosage will depend on the age of the patient. For children up to three years of age, I have begun with a dose of from 0.5 to 1 gm. of the ammonium salt four times a day, and if necessary have increased the dosage to 1.25 gm. four times a day. The child from four to eight years of age should have 1.5 gm. four times a day. Children more than ten years of age start with 2.5 gm. four times a day and can tolerate up to the full adult dose. Ammonium mandelate in these dosages usually will render the urine sufficiently acid to make administration of additional acid-forming salt unnecessary. If the necessary acidity is not reached after two days, ammonium nitrate or ammonium chloride, 0.5 gm. four times a day should be added. Administration of the drug is continued for forty-eight hours testing the pH of the urine each day. After forty-eight hours a culture is taken. If the pH has fallen to between 5 and 5.5 it is likely that the culture will be sterile. If after twenty-four hours, the urine is sterile on culture of 0.5 c.c., the same dose may be continued for another seventy-two hours, the acidity should be checked daily, and cultures of the urine should be made on the fourth or fifth day. If the urine is still sterile, all medication may be omitted, and the urine may be cultured after an interval of seventy-two hours. If the urine is then sterile, the infection has probably been eradicated. If possible, cultures should be made again a week after treatment is discontinued.

When there is no obstruction in the urinary passages this cure is usually permanent. On a number of occasions, when the infection has recurred, it has been eradicated by the same mode of treatment. If the patient's urine remains sterile for a number of days following discontinuance of administration of the drug, the condition should be considered cured. The chronic recurrence of the infection is fairly good evidence that there is some focus which is periodically introducing bacteria, and these, when once back in the urinary passages, can maintain themselves, with or without stasis.

If the infection has been cleared up in a case in which stasis is present, the correction of the stasis should be under-

taken immediately to prevent further injury to the kidneys by back-pressure. When the infection has disappeared, it may be more difficult to persuade the patient or his guardians to undergo the operation, but the advantage of operating on a sterile urinary tract is well worth working for.

The relief of urinary stasis must be left to the urologist, but it should be urged on the patient or his guardians that only by early relief of obstruction can renal function be preserved.

After operation it may again become necessary to sterilize the urine by the administration of ammonium mandelate.

#### SUMMARY

Persistent pyelitis is either the result of faulty treatment or of urinary stasis. During childhood many patients with urinary stasis can be freed from the infection. It is essential to remove the obstruction at the earliest possible moment. Administration of ammonium mandelate, the ketogenic diet, and methenamine, in the order named, are the most useful procedures for combating urinary infections.

## DIAGNOSIS OF ABDOMINAL ENLARGEMENTS IN CHILDREN

SAMUEL AMBERG

---

THE size and configuration of the abdomen are determined by the thickness of the abdominal wall and the tonus of its muscles, by its skeletal delimitations and by the characteristics of the contents of the peritoneal cavity. In the newborn infant the transverse and anteroposterior diameters above the umbilicus are greater than in older individuals, and are also greater in relation to the length of the peritoneal cavity and body. During childhood the panniculus adiposus of the abdominal wall of girls is somewhat thicker than that of boys.

During the first years of childhood the abdominal profile usually protrudes further forward than that of the chest. After about the second year, the circumference of the chest exceeds that of the abdomen. Changes in the size of the abdomen resulting from changes in posture are not pertinent to this discussion.

Enlargement of the abdomen may be due to excessive deposition of fat in its walls. Such deposition may be uniform, or the abdomen may be unduly prominent in one place, as for instance in the region below the umbilicus. Deposition of fat may occur as part of constitutional obesity, the etiology of which has hitherto been poorly understood, or it may be associated with endocrine disorders.

The abdomen, for topographic purposes, has been divided into several regions which have been designated the epigastric, umbilical and hypogastric, and the right and left hypochondriac, lumbar, and iliac regions. Enlargement of the abdomen may be evident in only one region, but usually it is more generalized. Enlargement may be due to several factors. For example, a tumor may be present in association with

ascites or with intestinal distention due to obstruction or both. Abdominal enlargement of a high degree can be recognized without difficulty, but enlargement of slight degree may escape notice. The size of the abdomen may be increased by meals, by filling of the intestines, by filling of the bladder, or by accumulation of gas in the intestines. It is therefore not surprising that measurements of the abdomen are omitted in tables of growth and are not mentioned in case reports except when the size is excessive. Parents may fail to note the development of abnormal degrees of abdominal enlargement in children when the enlargement appears gradually.

Enlargement of the abdominal wall as a result of thickening other than that due to obesity may be localized or diffuse. Such enlargement includes inflammatory swellings, with or without abscess formation. Inflammations in the umbilical region of the newborn are now seen only infrequently. Erysipelas occasionally produces swelling of the abdominal wall. Erysipelas has been seen in two infants, extending from the vulva to the abdominal wall; in the course of the illness purulent peritonitis and dynamic ileus developed, after which most of the abdominal enlargement was attributable to their presence. The diagnosis in such cases is usually self-evident. Peritonitis in the newborn infant can originate in infections in remnants of the omphalomesenteric arteries or of the umbilical vein. The point of origin, under such conditions, may not be recognizable during life. Localized enlargements may be caused by congenital umbilical hernias; for instance, a hernia into the umbilical cord may be very large, and in addition to intestinal loops, may contain other organs such as the liver. Tumors of the umbilicus in the newborn are usually small. An umbilical hernia may progress to partial or complete eventration, which in turn may be accompanied by distention of the intestines.

Angioneurotic edema can occur in the abdominal wall and thus produce localized single or multiple regions of enlargement. Recognition of such swelling as urticarial may be aided by the presence of urticaria-like swellings in other regions of the body, by their transient nature, and by their itching.

Definitely localized enlargements may be caused by tumors of the abdominal wall. A good illustration of such enlargements, resulting from a neurofibroma, is given in

Schultz' chapter on tumors in children in Abt's System of Pediatrics. Lipomas can also produce enlargement of the abdominal wall.

Diffuse enlargement of the abdominal wall, if not attributable to obesity, is usually due to edema, which may be very marked. It occurs most frequently in patients suffering from circulatory failure, from nephrosis, or from nephritis. Edema of the abdominal wall in cases of hepatic disease is usually not so great. It may become more prominent as the disease advances. Often in such cases the enlargement of the abdomen is due not only to edema of the wall but also, to some extent, to peritoneal effusion. In cases of nephrosis, acute peritonitis may supervene, thus adding distention of the intestines to the already present enlargement. Clinically it is not always easy to distinguish edema of the abdominal wall from peritoneal effusion, or to estimate how much of an enlargement is due to one or the other factor. In testing for undulation it is well to have an assistant exercise linear pressure on the middle of the abdomen. At times edema of the abdomen of the newborn infant occurs as part of hydrops universalis. This is also usually accompanied by peritoneal effusion. Such infants when not stillborn, die within the first few days of life. There is another form of edema accompanied by peritoneal effusion which occurs rarely during infancy. The etiology is unknown.

Lack of tone of the muscles of the abdomen may result in its enlargement. The abdominal distention of rickets, celiac disease and occasionally of diseases of the central nervous system such as infantile paralysis, has been ascribed in part to weakness of the abdominal muscles.

Enlargement may be caused by disease of one or the other of the organs located within the peritoneal cavity. Such enlargement may be unilateral, or limited to a particular region or regions. Thus, diseases of the liver may be associated with prominence of the right hypochondrium and the epigastrium. Hypertrophy of the liver in cases of cirrhosis can produce fullness in these regions, although a considerable degree of enlargement of the liver may be present without producing definite fullness until portal hypertension results in ascites. In one of our cases at the clinic, that of a boy aged twelve years, a visible tumor-like mass was present in the epigastrium. It

proved to be the left lobe of a cirrhotic liver. Syphilis of the liver may also produce visible enlargement.

In infants and younger children enlargement of the abdomen may be secondary to enlargement of the liver by fatty infiltration, or by excessively large deposits of glycogen ("glycogen storage disease," Van Gierke). In such cases the values for fasting blood sugar may be below normal and may rise little or not at all on administration of epinephrine.

In infants, Niemann-Pick's disease, a type of reticulo-endotheliosis, may be associated with enlargement of the liver of sufficient degree to cause visible protrusion of the abdomen.

Tumors of the liver may produce bulging of the abdomen. Primary carcinoma and sarcoma of the liver occur even in early infancy. Hemangiomas and hemangio-endotheliomas, although of uncommon occurrence, have been observed most frequently in early infancy. Leukemic infiltrations and Hodgkin's disease of the liver may cause the abdomen to protrude over the site of that organ. This may happen also in some forms of anemia, such as Cooley's. Metastatic tumors such as neurocytomas from the suprarenal gland may also cause visible protrusion.

Multiple abscesses of the liver very rarely cause visible enlargement of the abdomen in children. Abscess of the liver due to *Endamæba histolytica* is not common in childhood. Such an abscess may occasionally become so huge as to cause visible enlargement of the abdomen and fluctuation. The diagnosis usually depends on a history of dysentery and on the demonstration of amebas in the stools.

Cysts of the liver sometimes cause very marked abdominal distention. An instance of this was observed in the case of a girl, aged three years, whose abdomen had gradually enlarged. On palpation a circumscribed fluctuating tumor was found, which seemed sharply separated from the liver. The clinical diagnosis of ovarian or mesenteric cyst was not substantiated at operation, at which time a large cyst of the liver was found. The liver was very large and contained at least one other large cyst. The larger cyst was drained, and continues to discharge after eight years. The abdominal enlargement has decreased and the girl now regularly attends school. This case illustrates the fact that when a cyst is so large as to fill the ab-

domen, it is hardly possible to determine the organ from which it takes its origin. In the earlier stages of development of a tumor, the location as determined by palpation may help to determine the organ from which it originates as well as its probable character. In contradistinction to solitary cysts, which may be single or multiple, generalized cystic disease of the liver may be present and may cause visible enlargement. The solitary cysts may be lined with ciliated epithelium. Cysts of the liver may be caused by echinococci. The finding of a specific precipitin reaction of the patient's serum or a positive Casoni cutaneous reaction is of great value in the diagnosis.

During childhood, diseases of the large bile ducts or of the gallbladder rarely lead to visible change in the contour of the abdomen. Cysts of the common duct, of unusually large size, may cause visible swelling. If pain and intermittent attacks of jaundice are associated with such visible swelling, they may aid in the preoperative diagnosis.

Very rarely a cyst of the pancreas may become sufficiently large to cause abdominal enlargement.

The spleen may enlarge so greatly as to be visible. This may occur in patients with malaria, and in patients with leukemia, particularly the myeloid form. In both instances, examination of the blood should give information on which a definite diagnosis can be based. The same remarks apply to kala-azar, which is very rare in the United States. Visible enlargement of the spleen may be present in the course of familial hemolytic icterus, particularly during a crisis. Very marked enlargement of the spleen may be associated with thrombophlebitis of the splenic vein. The vascular occlusion may be suspected if hematemesis occurs early in the disease. If such a splenic tumor becomes palpably smaller after intramuscular injection of epinephrine it is likely to be due to vascular obstruction. Malignant disease, primary in the spleen, as for example sarcoma, is extremely rare.

An enlargement of the spleen may become visible in Gaucher's disease which can occur in childhood. Cysts also occur in the spleen. The tests already mentioned may be used to determine whether such cysts are due to echinococci. Echinococcus cysts of the spleen are much more rare than

echinococcus cysts of the liver. In the case of a boy, aged eight years, a diagnosis of cysts of the spleen was based on the findings of bulging of the left hypochondrium and flank and splenomegaly. The diagnosis was confirmed at operation. The cyst contained blood. The histopathologic diagnosis was not positive; it was thought to be hemangioma. The cause and often the exact nature of such splenic cysts is obscure, and the diagnosis is often made only at the time of exploratory operation. In the case just cited, the mother noted abdominal swelling ten months before her son's admission, and jaundice, of a week's duration, six months before admission.

Enlargement of the organs of the genito-urinary tract as a result of disease may cause abdominal enlargement. It is a well known fact that a distended urinary bladder may cause prominence of the lower part of the abdomen, and that such prominence is not always in the midline. It may be found at any age. Catheterization, or catheterization and manual expression, will result in prompt disappearance of the swelling. Ureters which are greatly dilated may lead to some fullness of the lower part of the abdomen. It is also common for a hydronephrotic kidney to cause bulging of the abdomen. This bulging is usually unilateral and in the flank. Disappearance of the swelling following copious urination should suggest the diagnosis, which, like that of a megalo-ureter, can be definitely established by urologic examination.

Cysts of the kidneys may be of sufficient size to cause abdominal enlargement. They may be unilateral or bilateral. If they are of the solitary type they may not interfere with the function of the kidneys. The location and consistence may suggest the true nature of the swellings. Since they are not radiosensitive, therapeutic application of roentgen rays is of aid in differentiating them from malignant tumors of the kidneys.

Malignant tumors of the kidneys of children are not extremely rare. They are usually of a mixed type and are often designated as Wilm's tumors. Children with Wilm's tumors frequently are not brought to a physician before abdominal fullness has become noticeable. The tumors are usually very firm, although they may contain cystic areas of degeneration. Hematuria is of infrequent occurrence in patients with Wilm's

tumor, but if present, is of diagnostic importance. A roentgenogram of the abdomen or urologic examination may reveal distortion of the renal pelvis, which is of diagnostic help in localizing renal tumors of a cystic kind, or other kinds.

Cysts of the urachus have been found in children with abdominal distention. The diagnosis in some cases is uncertain and can hardly be made without exploratory operation. Tumors of the bladder that cause abdominal enlargement in children are very rare. Occasionally a malignant tumor of the prostate gland, such as a sarcoma, may cause abdominal enlargement, which is made up in part by metastatic nodules, by ascites, by distention of the intestines, and by edema of the wall. These tumors, too, are of very infrequent occurrence in children. The first symptom may be dysuria. Catheterization may be difficult because of obstruction. A mass may be palpable by rectal examination.

Tumors of the ovaries, especially cysts, are more common in children. Because of their presence, abdominal enlargement may be very great. The finding of a circumscribed tumor which arises from the midline of the pelvis, which is circumscribed and which dents readily but does not exhibit movable dulness, should suggest the presence of an ovarian cyst. A large flaccid cyst may simulate ascites with undulation or ascites which is so marked as to exhibit no movable dulness. Other malignant tumors may arise in the ovaries. We at the Clinic have seen a teratoma attached to the wall of the bladder of a girl aged eight years, whose abdomen below the umbilicus was considerably enlarged. If roentgenograms reveal the presence of bony material in such tumors, their nature may be more strongly suspected.

Affections of the intestinal tract often account for enlargement of the abdomen. With the exception of umbilical hernias which, in infants, do not often attain great size, direct hernias through the abdominal wall in children are rare. Occasionally a large, postoperative direct hernia may develop. Enlargement of the abdomen that takes place following incarceration of an intra-abdominal hernia is due primarily to the intestinal obstruction.

In young children, pyloric stenosis or obstruction of the duodenum may cause a protuberance in the epigastrium. The

visibly distended stomach may make the upper part of the abdomen of an emaciated infant very prominent as compared to the sunken-in lower portion. The diagnosis of pyloric stenosis is aided by the presence of visible peristalsis of the stomach with waves that travel from left to right, by projectile vomiting and, less frequently, by a palpable mass in the region of the pylorus. After operation visible distention of the stomach may take place. This occurred in the case of one infant operated on for pyloric stenosis.

In some instances abdominal enlargement results from distention of the intestine above the point of an obstruction, partial or complete. The obstruction may be caused by congenital atresia. If atresia involves the anus, intestinal stasis and distention are usually absent because the fistulous channel that develops between the rectum and urinary tract allows escape of intestinal contents. Partial obstruction of the intestine may be due to a variety of lesions, such as incarcerated hernias, fibrous bands that constrict one or more loops, volvulus, tumors both extrinsic and intrinsic, and segmental inflammation. In addition to causing distention of the bowel, obstruction may cause visible peristalsis of the dilated portion, and borborygmi may be very noticeable. If the obstruction becomes complete, the abdominal distention may be very great. Cessation of bowel movements, absence of fecal matter from the lower part of the intestine, vomiting of fecal material, rapidly developing emaciation and desiccation, are the most striking features of such mechanical ileus.

In older infants acute intussusception is perhaps the most frequent cause of partial or complete intestinal obstruction. Intermittent attacks of apparently severe pain, which begin suddenly and which are associated with crying, particularly at the age at which the infant begins to walk, are often the first symptoms. Soon after the appearance of these symptoms blood or bloody material is passed from the rectum. The child may vomit. Between attacks of colicky pain when the abdomen may be soft, a sausage-shaped mass may be palpated. This is usually felt first in the right ileocecal region. Fluoroscopic examination together with inflow of contrast material can be of great value. After a shorter or longer period of time the intestines and abdomen become distended. Intussuscep-

tion may occur also in later childhood. Chronic intussusception occurs much less frequently, and is usually initiated by some lesion of the intestinal wall such as a polyp. In one case observed at the Clinic a lymphoma was the cause of chronic intussusception which was associated with a considerable degree of abdominal distention. The clinical picture may be difficult to analyze.

Intra-abdominal cysts may originate from a Meckel's diverticulum, or from some other part of the intestines, from the mesentery, or from the omentum. These, even in very young patients, can cause abdominal enlargement, either by their size or by causing intussusception or obstruction. We have observed a cyst of the omentum in a girl aged four years. An enlarged abdomen was noted about ten months before admission. On examination a large, rather flaccid cystic mass was found. At operation two rather large cysts were found: the larger contained 2,800 c.c. of bloody fluid. The smaller cyst was ruptured during operation. Cysts of the mesentery are likely to be multiple.

Tumors of the intestines may be responsible for abdominal enlargement. The most common types are lymphomas or lymphosarcomas. In the case of a boy, aged thirteen years, the cause of abdominal distention was found to be widespread lymphosarcomatosis of the intestines and mesentery. In this case the distention was due to the presence of fluid in the peritoneal cavity as well as to the presence of the tumors.

Abscesses within or adjacent to the peritoneal cavity may be of sufficient size to produce abdominal enlargement. This may occur, for example, in the case of a psoas abscess of tuberculous origin. The finding of tenderness over the spinal column and the demonstration by roentgenography of a lesion of the vertebrae are of major importance in determining the nature of the process. If in such a case the intracutaneous tuberculin reaction is repeatedly negative, a diagnosis of tuberculosis becomes uncertain. Appendicitis, with perforation of the appendix, is perhaps the most frequent cause of enlargement of the abdomen due to purulent exudate in the peritoneal cavity. Following subsidence of the immediate generalized inflammation, localized protrusion of the abdomen may become visible. This is present most frequently on the right side of

the abdomen, but it may extend beyond the midline and may even be more prominent on the left side. A history of pain and tenderness in the region of the appendix is of the greatest value in diagnosis. The character of the temperature curve and the blood picture will probably indicate the purulent nature of the condition. Large abscesses may come from other sources, such as areas of osteomyelitis.

Enlargement of the abdomen due to distention of the intestines without obstruction occurs very frequently. Pain, if present, disappears as flatus escapes from the bowel. Distention of this sort as a rule does not persist. Palpable masses, tenderness, and signs indicative of effusion are lacking. It is of frequent occurrence during the course of infectious diseases such as pneumonia and may contribute to embarrassment of respiration. It is of not infrequent occurrence after operations. This kind of distention combined with weakness of the abdominal muscles has been thought to account for abdominal enlargement in rickets and in celiac disease. Persistent distention of segments of the small intestines may occur without any demonstrable cause.

The most marked degrees of abdominal enlargement are found in cases of Hirschsprung's disease (megacolon). A thin abdominal wall, resulting from the emaciation which is usually present, allows the pattern of the intestinal loops and their peristaltic constrictions to be easily visible. The enlarged abdomen may be pear shaped, with the wider portion uppermost. A history of absence of spontaneous bowel movements from the time of birth or early infancy is of greatest diagnostic significance. In some cases canalization of the retained fecal material may permit the occurrence of diarrhea. The huge masses of retained fecal material are usually palpated with ease, and after repeated and properly administered enemas they disappear. Roentgenologic examination of the colon is of great value in diagnosis. However, a false impression of dilatation of the colon may be obtained from examination of the roentgenogram alone. It is therefore very important, particularly when the diagnosis is somewhat doubtful, to have a fluoroscopic examination. It is also of importance to decide whether the dilatation involves the entire colon or only a segment of the colon. On this finding may

rest the decision as to the advisability of sympathectomy or resection of the colon.

An excessive amount of fluid in the peritoneal cavity, either alone or together with other factors such as distention of the intestines and tumors, is a very frequent cause of abdominal enlargement. Excessive amounts of fluid may accumulate as a result of inflammatory processes of the serosa, diseases of the kidneys, or interference with the circulation of blood and lymph. The character of the fluid differs according to the source and cause of its derivation. If the fluid is a transudate, such as that formed in cases of circulatory obstruction, the protein content will usually be found to be less than 3 or 4 gm. per 100 c.c. If the fluid is composed of inflammatory exudate, the protein content is greater. The lowest value for protein content, 0.5 gm. per 100 c.c. or less, is found in the opalescent ascitic fluid from patients with lipoid nephrosis. In cases of nephritis and in cases in which there are circulatory disturbances the fluid is usually clear. An exception to this is the fluid from patients with chylous ascites, but this is very uncommon. The ascitic fluid in this condition is milky, and if ether is added to it, it becomes clear. In the presence of tumors the ascitic fluid may be brown or bloody.

Free fluid in the abdomen, if not too great in amount, is indicated by dulness to percussion. This dulness moves as the patient changes position. If the abdomen becomes tense because of the accumulation of fluid, percussion will yield a note which is dull regardless of the position assumed by the patient. In such cases the presence of fluid can be more reliably determined by the elicitation of undulation, or fluid waves, by the proper maneuver. It has been mentioned that large cysts with flaccid walls may be confused with collections of fluid in the peritoneal cavity.

Large amounts of fluid may be associated with protrusion of the navel.

Circulatory disturbances which lead to the accumulation of fluid may be divided into two main groups: those due to portal hypertension, and those in which the circulatory obstacle is intrathoracic. The latter may be either a failing heart or narrowing of the inferior vena cava in patients with adhesive pericarditis.

Portal hypertension resulting from thrombosis of the portal vein occurs rather infrequently, particularly in children. In such cases the ascites develops rapidly. However, this may occur in other conditions. I saw one case in which thorough exploration did not reveal an adequate explanation for the rapidly developing ascites.

Portal hypertension as a rule is due to diseases of the liver which will be designated here collectively as "juvenile cirrhosis" without any attempt to subclassify. As fluid accumulates from any cause, the abdomen distends and the navel may protrude. In cases of portal hypertension, visible collateral circulation in the umbilical region, the caput medusæ, is commonly observed. This need not occur in every case, since the path of the collateral circulation may be deep in the abdominal cavity. Collateral circulation visible on the sides of the abdomen is more likely to be caused by an obstruction in the abdominal, inferior vena cava. Edema of the lower extremities and of the abdomen may occur late in the disease and may be due to various factors which do not concern us here. A history of jaundice, early enlargement of the spleen (common in juvenile cirrhosis), and various tests of liver function, aid in the diagnosis. The liver is usually enlarged.

In very rare cases congenital obstruction of the hepatic veins at their entrance into the vena cava may exist and may lead to abdominal enlargement. Obstruction of the vena cava in cases of adhesive pericarditis or "inflow stasis" is not always easy to differentiate from portal hypertension. The disease is more common in later childhood and early adolescence. Signs of valvular heart disease may be absent. In patients with constrictive pericarditis the respirations are usually easily embarrassed; there may be some cyanosis, and edema of the lower extremities may appear early in the course of the disease. Venous pulsation in the neck occurs only. Effusion into the pleural cavities is not an uncommon finding. In the few cases which I have seen, no collateral circulation was visible. The sluggish circulation causes the liver to enlarge soon after the onset of the disease. In one of our cases at the Clinic the surface of the liver became uneven and signs of impaired liver function were found. In this case a considerable degree of obstruction was found at operation. The constricting tissue was

partly calcified. In another case calcification of the pericardium was visible in the roentgenogram. The only effective treatment is surgical.

Ascites that develops in patients with nephrosis is usually associated with edema of the legs and abdomen. The urine usually contains considerable amounts of protein and large numbers of casts, and may contain lipoids which are doubly refractive. Increased values for blood lipid and cholesterol are of diagnostic significance. Other forms of ascites due to renal disease can be differentiated from nephrosis by the different findings in the urine, by the presence of elevated blood pressure, and by the demonstration of impaired renal function.

Obstruction of lymph channels may cause chylous ascites. In the case of a boy aged eight months, enlargement of the abdomen was found to be due to such an ascites. At necropsy the thoracic duct could not be demonstrated.

The subject of tuberculous peritonitis deserves special attention. It occurs in the two main forms, the dry and the ascitic. However, there may be a combination of these. The ascites usually develops insidiously and may be accompanied by progressive emaciation. It has been stated that rapidly developing ascites in children is usually due to tuberculous peritonitis. This may be true in regions in which tuberculosis is unusually prevalent. Pain and tenderness frequently are absent. The onset may be stormy, and may simulate that of an infectious disease like typhoid fever, or it may be gradual as in other forms of acute peritonitis. The dry form is characterized by the formation of fibrous tissue. Abdominal enlargement may be the first and only symptom. The intestinal coils, thickened by fibrotic tissue, may form irregular protruding masses. The omentum may become fibrotic and cause protrusion of the upper portion of the abdomen. The enlargement of the abdomen may be increased by ascites which is sometimes transitory in nature. The diagnosis of tuberculous peritonitis is made more probable by a history of contact with tuberculosis, by the demonstration of tuberculous lesions elsewhere in the body, and by a positive intracutaneous tuberculin reaction. If tubercle bacilli can be demonstrated in the fluid or lesions the diagnosis becomes certain. Guinea-pig inoculation is usually required for such proof.

Purulent peritonitis may be due to a variety of organisms, of which streptococci, pneumococci and colon bacilli are the most common. The mode of invasion is not always apparent. It may occur as a result of perforation of the intestinal tract by trauma or ulceration. The organisms may reach the peritoneum through the blood stream, through lymph channels, from a ruptured abscess, or possibly by transmigration. The diagnosis of acute purulent peritonitis is relatively simple in cases with the characteristic increase of muscle tension, the pain, the rebound tenderness, the vomiting, fever and polymorphonuclear leukocytosis. Usually there is constipation, but there may be diarrhea. It is well to remember that the picture may not be complete. Enlargement of the abdomen is usually due more to distention of the intestines than to the amount of purulent fluid. If the peritonitis is due to pneumococci, the amount of pus may be sufficiently large to produce abdominal enlargement. Diagnostic aspiration of the intraperitoneal material has been recommended.

Abdominal enlargement due to hemorrhage into the peritoneal cavity may occur after trauma. The most frequent cause is rupture of the spleen. The history of an injury, the location of the injury, and evidence of rapid loss of blood are the most important diagnostic features. Definite diagnosis usually cannot be made before exploratory operation is performed.

## DISEASES OF THE THYROID GLAND IN CHILDREN

ROGER L. J. KENNEDY

---

IN order to understand better the morbid processes that occur in the thyroid gland and the clinical disturbances which result from these processes, it is well to have in mind certain facts concerning the anatomy, embryology, histology and physiology of that organ.

The gland is bilobed, the lobes being connected by a bridge of tissue, the isthmus, which crosses the midline of the neck, anterior to the trachea. Ordinarily, the lobes cannot be outlined by palpation, although the isthmus is frequently palpable and even visible.

The size of the organ varies with age, from birth to puberty. In the newly born it weighs from 1.5 to 2.5 gm. The weight increases to about 10 gm. by the tenth year and to about 15 gm. at puberty.

Four main arteries, two superior and two inferior thyroid arteries, together with the thyroid ima artery and other lesser arteries, carry the blood supply to the thyroid. The veins which arise in a rich plexus covering the gland, are the superior, lateral and inferior groups.

The gland receives its nerve supply from both the sympathetic system and the vagus nerves, chiefly from the former. The close relationship between the gland and the recurrent laryngeal nerve is of considerable clinical and surgical importance.

Accessory thyroid glands may be formed along the course of the thyroglossal duct, from the base of the tongue to the root of the neck. If the thyroid fails to progress in development beyond the tongue, there results an aberrant lingual thyroid. The close apposition of the thyroglossal duct to the hyoid bone accounts for the occurrence of accessory thyroids in the

region of the bone. This too accounts for the position of thyroglossal duct cysts (Fig. 38) and sinuses which are always in the median line near the hyoid bone. Other accessory thyroids may be found in close approximation to the pyramidal and lateral lobes and at the lower pole of the gland. From these may arise intrathoracic and retrosternal goiters.

Fig. 38.—Thyroglossal duct cyst of a boy aged twelve years. The cyst had been incised, following which it had healed and discharged intermittently. The characteristic position in the midline of the neck is well illustrated and serves to distinguish thyroglossal duct cysts and sinuses from brachial cleft and other kinds of cysts.

The occurrence of a pyramidal lobe or of a persistent thyroglossal duct is based on the following embryologic facts. The thyroid arises from the floor of the pharynx. It develops as a stalk with a globose end. Under ordinary conditions the stalk becomes obliterated and the globose end develops into the bilobed gland. If the connection between the stalk and the pharyngeal floor is lost near the pharynx, a pyramidal lobe or persistent thyroglossal duct may result.

The parenchyma of the gland consists of colloid-filled fol-

licles. The follicles are lined with epithelium made up of cuboidal cells.

The function of the thyroid gland, according to Plummer (1922), is the elaboration and delivery to the blood of a secretion containing its active principle, thyroxin, and the storage of colloid in its vesicles. Iodine is probably stored in the colloid.

When inorganic iodine is injected or given by mouth, it is taken up rapidly by the thyroid gland. Iodine in the inorganic form, however, is not present in the normal gland; it is found there only as a component part of organic compounds (Kendall). From 0 to 15 per cent of this organic iodine of the gland is to be found in thyroxin; the balance of the iodine is present in other compounds.

Iodine is present in the gland even before birth and increases in amount from birth to maturity. The amount is determined to some extent by the content in the diet and water supply. Sea foods are known to have a relatively high content of iodine. In order to maintain the required amount in the gland, a child must receive daily from 0.050 mg. to 0.150 mg. of iodine.

According to Plummer (1926) thyroxin functions throughout the cells of the body and does not primarily influence any one organ or system of organs. It functions not by producing energy itself, but by raising the capacity of any given cell to respond to excitation or stimulation.

If the thyroid gland is removed from young animals a striking series of changes takes place. There is retardation of growth and depression of all of the physiologic functions of the body. Growth of bone slows up, the hair becomes dry and coarse and the muscles become weak and flabby. Movements become sluggish. The temperature is lowered and pulse slowed. Sexual function fails. There develop an increased tolerance for carbohydrates and an increased storage of glycogen in the liver. The basal metabolic rate is lowered as much as 40 per cent or more.

Thyroidectomy in children is followed by a picture similar in all respects to that observed in young animals. In addition to retarded physical growth and depressed physiologic functions, various kinds and degrees of mental disturbance may

develop. Examination of an individual so affected may reveal a sluggish, apathetic, sleepy person. The hair may be coarse, the skin dry, the features heavy, and the expression dull. The body temperature is low, the perspiration decreases, the patient may complain of sensitiveness to cold, and anorexia and constipation are common. Pads of tissue, simulating fat, appear especially above the clavicles. These are referred to as myxedematous pads, the nature of which is unknown.

Feeding of large amounts of thyroxin to young animals does not result in a condition exactly the reverse of that brought about by insufficient thyroid material. There is a diminished rate of growth and hypertrophy of certain organs such as the testes and ovaries, the suprarenal glands, the heart, the liver, the pancreas and the spleen. The thyroid gland decreases in weight and activity, although the metabolic rate increases. If feeding of thyroid is discontinued, the rate of growth is accelerated and hypertrophy of the organ subsides.

Administration of large amounts of thyroid material to human beings is seldom continued for any length of time. It results in serious phenomena such as tachycardia and arrhythmia, vertigo and weakness, excessive perspiration, diarrhea and generalized pains.

In young individuals, from whom the thyroid glands have been completely removed, restitution to normal can be brought about by administration of thyroid material. If young individuals have been deprived of thyroid material for some time, the restitution will be only partial.

Complete absence or lack of function of the thyroid gland results in lowering of the basal metabolic rate to a level of from 40 to 45 per cent below the average of normal individuals. In patients whose thyroid glands are overactive the basal metabolic rate may be elevated to as much as 100 per cent above normal. In recent years considerable investigative work has been done which is purported to demonstrate certain relationships between the glands of internal secretion. Perhaps the most important of these concerns the claims which have been made for the existence of a hormone, the so-called "thyrotropic hormone," present in the pituitary gland, which controls the activity of the thyroid gland. In spite of the evidence that has been offered to support the claim of the existence of such

a hormone in lower animals, there is very little evidence that it is present in human beings, or if present, that it is of any clinical importance.

### DISEASES OF THE THYROID GLAND

As a working classification of diseases of the thyroid glands of children, the following is offered:

- Congenital goiter
- Diffuse colloid goiter
- Adenomatous goiter (without hyperthyroidism)
- Exophthalmic goiter
- Hypothyroidism
- Cretinism { Athyreotic
- Endemic
- Myxedema
- Inflammation (thyroiditis)
- Malignant diseases of the thyroid.

#### CONGENITAL GOITER (CONGENITAL HYPERTROPHY, NEONATAL STRUMA)

Congenital goiter, which consists of enlargement, in part or in whole, of the thyroid gland of the newly-born child, is to be distinguished from the enlargement attributable to congestion and from that found in patients with endemic cretinism. The upper limit of weight of the thyroid gland in newly-born infants varies in different countries from 2.5 gm. up to 6 gm. Weights exceeding these figures are probably abnormal and the glands represent congenital goiters.

Deficiency of iodine in the mother may be responsible for goitrous infants. Since the incidence is higher in regions where goiter is endemic than elsewhere, it may be assumed that the causes, whatever they may be, are the same as those which produce other endemic goitrous diseases.

The gland, in part or in whole, is large, firm and regular or irregular. Dyspnea of varying degree may be present. Death may result from obstruction of the respiratory tract.

In general the more marked the enlargement, the greater is the danger to the life of the infant; the mortality may be as high as 60 per cent. Usually there is spontaneous regression in the size of the gland.

The administration of iodine in a dose of 10 mg. three times

a day to a pregnant woman, from the third or fourth month antepartum, has been advised to eliminate the possibility of congenital goiter.

Intubation, tracheotomy and resection of the thyroid isthmus have been employed in treatment. If the enlargement persists beyond the first few weeks of life, treatment with iodine and thyroid material may be administered.

#### GOITER (STRUMA, BRONCHOCELE, DIFFUSE COLLOID GOITER)

The term, "diffuse colloid goiter," indicates a diffuse symmetrical enlargement of the thyroid gland (Fig. 39), the acini

Fig. 39.—Diffuse colloid goiter of a boy aged seven years. *a*, Before, and *b*, two months after start of desiccated thyroid therapy. In addition to diffuse enlargement of the thyroid gland, there was a lowered basal metabolic rate ( $-20$  and  $-22$ ) and clinical evidence of hypothyroidism. The blood cholesterol at the time of admission was 211 mg per cent. Roentgenograms of the wrist showed delayed ossification of the carpal bones. Reduction in the size of the gland and marked general improvement resulted promptly from treatment.

of which contain an excess of colloid; the enlargement is unassociated with symptoms of hyperthyroidism. It is variously referred to as "adolescent," "adolescent colloid," "vascular

colloid," "vascular adolescent colloid" and "simple" or "endemic goiter without adenomas or hyperthyroidism." Although endemic in some areas, it may be found in any part of the world.

Diffuse colloid goiter is the type of enlargement of the thyroid gland that has served as the subject of many surveys among children, particularly of those at or near the age of puberty. The use of different standards for diagnosis has resulted in some difference of opinion regarding the incidence of the condition. Suffice it to say that definite enlargement of the lobes of the thyroid gland has been of common occurrence among children, especially of those at or near the age of puberty.

The cause of this enlargement has not been definitely established, although the view that it is attributable to some deficiency, probably of iodine, is generally entertained.

The symptoms and signs which it may cause are chiefly local. The gland is found to be smooth and bilaterally and symmetrically enlarged; the enlargement may be slight or extreme. The gland is soft and compressible. The superior thyroid arteries may be so large as to be palpable, and a bruit and thrill may be present. The patient may complain of a feeling of fullness in the neck. The basal metabolic rate may be slightly depressed.

Sometimes the gland recedes spontaneously. By treatment it can usually be made to recede within a year. If such glands of children have been reduced the children should be given prophylactic doses of iodine for several years afterward, in order to prevent return of the enlargement. Exophthalmic goiter, contrary to certain expressed beliefs, is not more likely to occur in patients who previously had an existing diffuse colloid goiter.

The prophylaxis of goiter is concerned chiefly with the diffuse colloid type. The most important prophylactic measures which have been employed are the addition of iodine to water supplies, the use of iodized table salt, the use of tablets that contain iodine (iodostarin tablets contain 1 to 4 mg. of iodine), the use of compound solution of iodine (Lugol's solution) (from 3 to 5 drops once a week), the use of hydriodic acid (1 teaspoonful once a week), and the use of desiccated

thyroid. Iodized table salt, which is now so commonly used, is probably the simplest and most economical of the prophylactic preparations.

In the early stages of the development of the condition iodine in prophylactic doses may be curative. Desiccated thyroid gland administered orally in a dose of 1 to 2 grains (0.065 to 0.12 gm.) daily is the treatment of choice in well developed cases. In order to check the potency of the thyroid preparation and to maintain the metabolic rate at or near normal, it is desirable that frequent determinations of the basal metabolic rate be made. Only rarely need children be operated on.

#### ADENOMATOUS GOITER WITHOUT HYPERTHYROIDISM

Adenomatous goiter is a nodular enlargement of the thyroid gland caused by the presence of single or multiple aden-

Fig. 40.—Colloid and fetal adenoma in a diffuse colloid goiter of a girl aged twelve years. Nodules of this sort are rare among children and in our experience have more frequently been proved to be malignant than benign. The appearance may be similar in all respects to that of malignant nodules

omas within its substance (Fig. 40). Although in adults it is frequently accompanied by symptoms of hyperthyroidism, in

children it causes no constitutional symptoms. In other words, the syndrome of adenomatous goiter with hyperthyroidism has not, in our experience at the Clinic, been observed in children.

Although adenomatous goiters of clinically recognizable size occur with greater frequency in regions where goiter is endemic than elsewhere they are rare among children in the United States. They may occur in diffuse colloid goiters and remain unrecognized until the excess colloid disappears spontaneously or following treatment. The fact that they are more common in regions where goiter is endemic than elsewhere indicates that their etiology is the same as that of diffuse colloid goiter.

The adenomas give rise to few signs or symptoms other than visible and palpable nodular swelling of one or both lobes of the thyroid gland. Symptoms that result from pressure on the trachea or on the recurrent laryngeal nerve may be produced, and may be not only troublesome, but even serious.

Pathologically, the adenomas may be of the encapsulated ("fetal" or "adult") type, or as some observers hold, they may consist of noncapsulated nodular portions of thyroid tissue.

Removal of adenomas of the thyroid gland of children is justified for two reasons. Later in life the adenomas may require excision because of hyperthyroidism. Probably of even greater importance is the fact that carcinoma may be present in an adenoma without giving any indication of its presence. Timely removal of such a nodule offers a very good probability of complete cure.

#### EXOPHTHALMIC GOITER (GRAVES' DISEASE, BASEDOW'S DISEASE, PARRY'S DISEASE, HYPERTHYROIDISM, AND THYREOTOXICOSIS)

Exophthalmic goiter, according to Plummer's conception, is a clinicophysiologic complex similar to "that following the administration of thyroxin, or that associated with hyperfunctioning adenomatous thyroid, plus certain characteristic findings that can be grouped as ocular symptoms, the characteristic nervous phenomena, and the tendency to crises which may terminate in death." This conception applies to exophthalmic goiter of children as well as of adults.

The cause of exophthalmic goiter is not known. It is probable that the clinical picture is caused by an alteration in amount and character of the thyroid secretion. Disturbances of the sympathetic nervous system, constitutional predisposition, heredity, infectious diseases and nervous shock and stress may be contributory factors, but none of these alone or in combination can be considered as the fundamental cause of the disease.

There are no statistics available which indicate the frequency of exophthalmic goiter in the general juvenile population. At The Mayo Clinic, of 15,505 cases of exophthalmic goiter, slightly more than 1 per cent occurred among children aged fourteen years and younger. According to sex, the ratio of cases among female children to those among male children, as stated by different authors, is from 10:1 to 3:1. In our series of cases this ratio was 7.3:1. The disease may occur at any age. In children the frequency increases from birth to puberty.

Exophthalmic goiter in a child usually develops slowly, but its onset may be acute. In by far the largest number of cases the first symptom is nervousness. Next in frequency are goiter and exophthalmos. Tachycardia and tremor, although less frequent as initial symptoms, are usually noted before the disease has been present for a long time. Weakness, emesis, polyphagia, palpitation, loss of weight, dyspnea, diarrhea, excessive perspiration and intolerance to heat complete the symptom complex, and eventually become evident in a well developed case. In children the objective signs such as nervousness, goiter, exophthalmos, polyphagia, diarrhea and loss of weight may be present for some time before the child complains of the subjective manifestations such as weakness, palpitation and dyspnea.

Enlargement of the thyroid gland is one of the most constant and earliest developments. It is usually bilateral and symmetrical, and usually involves the isthmus. The enlarged gland is firm. The enlargement is painless, and palpation elicits little or no tenderness.

Visible pulsations, palpable systolic thrills and audible bruits may be present over the arteries, particularly those of the superior poles. Since thrills and bruits may also be present

in cases of diffuse colloid goiter, their presence should not be depended on in making a diagnosis of exophthalmic goiter.

Local effects from enlargement of the thyroid gland are not as prominent as in adults. There may be a feeling of pressure in the neck, slight dysphagia or rarely hoarseness from involvement of the recurrent laryngeal nerve.

Tachycardia is present in practically all cases. In 98 per cent of cases the pulse rate was found to be 90 beats or more per minute, and in 80 per cent of cases it exceeded 120 beats per minute. In an appreciable number of cases it is excessive, ranging from 160 to 180 beats per minute. If any doubt exists regarding the influence of extraneous factors, such as excitement, as a possible cause for the tachycardia, the pulse rate should be determined while the child is asleep. If the rate is normal in sleep, the child probably does not have exophthalmic goiter. Palpitation is common, but children do not complain of it early in the disease, probably because they are less accustomed to interpret subjective sensations than are adults.

Evidence of cardiac embarrassment is frequently manifested as dyspnea. This is usually mild, but may be so severe as to constitute one of the chief complaints.

Cardiac dilatation and valvular insufficiency are of sufficient degree to be clinically demonstrable in about half of the cases. Their presence is indicated by expansive movement of the precordium, extension of the borders of the heart beyond normal limits, location of the apex beat well outside the nipple line, and systolic murmurs which are most frequent at the base of the heart.

The characteristic change in the blood pressure consists of an elevation of the systolic pressure and consequent increase in pulse pressure. In 75 per cent of 138 cases the systolic blood pressure was higher than 120 mm. of mercury, and in 68 per cent of the cases it ranged from 120 to 190 mm. of mercury. The height of the diastolic pressure is little affected. The mean pulse pressure in 130 cases was 63 mm. of mercury. Under basal conditions both the systolic and diastolic pressures are lower, but there is no appreciable decrease in the pulse pressure.

Nervous phenomena are the outstanding symptoms of exophthalmic goiter in children. They consist chiefly of excessive

movements and emotional instability. The excessive movements frequently simulate those of chorea and have led to erroneous diagnosis. They may be distinguished from the movements of chorea by their purposeful character. The child becomes restless, fidgety, difficult to control and he picks or pulls at clothes, toys, books and other objects. The disposition of the child may change from one that is quiet, reasonable and friendly to one that is excitable, irritable and fussy. Crying, quarrelsomeness, impatience, fury and rage may be exhibited. The child becomes unable to get along with the family and playmates. Changes in behavior may be so marked as to simulate a psychosis. Schoolwork becomes difficult and often has to be discontinued. Such nervous manifestations as these mentioned here may be expected in all except the milder cases.

Tremors, either fine or coarse, occur in a large majority of cases, and are likely to be exaggerated by voluntary effort. Other subjective nervous phenomena are increased speed of reflexes and flushing of the skin.

Exophthalmos, usually bilateral, but occasionally unilateral, is the most frequent, important, and striking ocular sign of exophthalmic goiter in children. It occurred in 83 per cent of cases. Its presence should always suggest the probability of exophthalmic goiter. Whether or not exophthalmos is present, the eyes may impart to the countenance a staring expression which by some is thought to be even more pathognomonic of the disease than is exophthalmos. This "stare" may disappear as the disease is controlled, although the exophthalmos may persist in gradually lessening degree for a long time. Frequent winking, inability to cause the eyes to converge, lagging of the upper lids as the eyes follow an object describing a downward course, widening of the palpebral fissure and wrinkling of the forehead and raising of the eyebrows when looking upward are ocular signs of secondary diagnostic importance. Edema of the eyelids is found in almost all cases in which exophthalmos is present. Paralysis of the extrinsic muscles of the eyes occurred only rarely in the series of children seen at the Clinic.

General weakness and easy fatigability are present in the majority of cases. The loss of strength is general and often is severe. As a criterion of loss of muscular strength, testing the quadriceps muscle is done most commonly. The child is

asked to step up on a chair. If exophthalmic goiter is present, the effort is attended by unsteadiness, a jerky, uncertain, upward motion, and a tendency to assist in the act by use of the hands. The unaffected child carries out the maneuver steadily, smoothly and without apparent effort. The test was found positive on slightly more than 50 per cent of 157 children who had exophthalmic goiter.

Loss of weight, in spite of an enormous appetite and the ingestion of large amounts of food, is almost pathognomonic of the disease in its early stages. The loss of weight is usually moderate or severe, and in 60 per cent of cases was so marked as to be noticed by the parents. In the later stages the thyroid intoxication may cause loss of appetite, nausea, vomiting (crisis) and consequent rapid loss in weight.

A gain in weight, in the presence of active exophthalmic goiter, may follow a period of rest, especially when this is combined with administration of iodine.

Polyphagia, which was present in 60 per cent of 157 cases, is prominent in the early stages of the disease. Late in the disease the appetite lags, and ingestion of adequate amounts of food is accomplished only with difficulty.

Spells of vomiting, diarrhea or both occur in about a third of the cases. A tendency to looseness and frequency of bowel movements may persist throughout the course of the disease.

The episodes of emesis and diarrhea may be only a part of the picture of crises of exophthalmic goiter, which is made up of fever ( $100^{\circ}$  to  $104^{\circ}$  F.), emesis, diarrhea, increased severity of the nervous and mental phenomena, prostration and sometimes death. Crises are less frequent and less severe among children than among adults. They occurred in 30 per cent of the cases of children in the Clinic series.

Although fever is not a symptom of exophthalmic goiter, there is excessive sweating and a subjective sensation of heat in a large proportion (68 per cent) of cases. This results in so-called "heat tolerance," the desire to do with fewer clothes, and the expressed preference for cool or winter weather. The skin may have an hyperemic appearance caused by the peripheral vasodilatation.

Alopecia occurs in some cases. The nails may be thin, wrinkled, furrowed or undermined.

Edema of the lower extremities may be found in the moderately severe or severe cases. The edema of the eyelids has been mentioned.

The most important laboratory aid in the diagnosis and treatment of exophthalmic goiter is determination of the basal metabolic rate. Boothby and his associates recently have established a new standard for basal metabolic rates which has been named "The Mayo Foundation Standard." The need for such a new standard has been particularly great for the determination of the basal metabolic rates of children. The data on which this standard has been constructed and the manner of its use may be found by referring to the published reports of Boothby and his associates. In children less than six years of age, only a closed room or box type of apparatus can be used, such as that described by Talbot. By the older DuBois standard the basal metabolic rates of seventy children who had received no previous medication with iodine ranged from 0 to +100. The mean metabolic rate in this group was +42. In a group of fifty children, who had received an appreciable amount of iodine previous to the determinations, the values ranged from -20 to +80, but the mean value was +33 as compared to a mean value of +42 in the group of children who had not received iodine. In eighty-one cases, after intensive treatment with iodine, the rates ranged from -40 to +80, and the mean value for the group was +21.

It is evident, therefore, that the basal metabolic rates of children who have exophthalmic goiter tend to be reasonably high (+42). It is further evident that by means of iodine the basal metabolic rate can be decreased to approximately half of the admission rate. This decrease in the metabolic rate by means of iodine has made it possible to carry out lobectomy or subtotal thyroidectomy without preliminary ligation of blood vessels or injection methods of treatment, and has resulted in a lower mortality in spite of the fact that much more formidable types of operation have been carried out.

Lymphocytosis and occasional glycosuria are the only important findings in the blood and urine.

Cases of frank exophthalmic goiter, in which exophthalmos, tachycardia, nervousness and enlargement of the thyroid gland are observed, offer no diagnostic difficulty. As Helmholtz

pointed out, the combination of enlargement of the thyroid gland and nervousness in a child should give rise to strong suspicion of exophthalmic goiter. Undue attention to certain features has led to diagnostic errors. The excessive movements, although not purposeless in character, have led to a diagnosis of chorea. The findings of tachycardia, dyspnea, cardiac enlargement, heart murmurs and elevated systolic pressure have resulted in a diagnosis of heart disease. Asthenia and loss of weight have been ascribed to infection although other signs of exophthalmic goiter were present.

The finding of an elevated basal metabolic rate to  $+30$ ,  $+40$  or more in a child is a strong indication of exophthalmic goiter, even in the absence of such signs as exophthalmos, stare, dyspnea and tremor.

According to H. S. Plummer, a favorable response following the administration of iodine, that is, a decrease of nervous phenomena, is the most valuable test available in the diagnosis of mild cases of exophthalmic goiter.

Exophthalmic goiter in children tends to be progressive. The longer the disease is present, the more deleterious is its effect on the organs and the body as a whole. Complete disability may develop within a year and death may take place in a crisis or from intercurrent infection or other complications. The use of iodine has greatly reduced the death rate, and pre-operative and postoperative crises following its use have become much more rare. In our experience it has permitted more extensive initial surgical treatment, and has reduced the surgical mortality in exophthalmic goiter of children from 9 to 2.5 per cent.

Occasionally mild exophthalmic goiter of children may be satisfactorily treated without resort to operation. In eight cases encountered at the Clinic the disease was successfully controlled by the use of iodine and reduction of activities.

In 97 per cent of 120 glands removed from children with exophthalmic goiter, the essential change was found to be diffuse parenchymatous hypertrophy and hyperplasia. The cells of the follicular epithelium were found to be high cuboidal or columnar, rather than low cuboidal, the type of cell characteristic of the normal gland. The epithelium revealed, as evidence of overgrowth, infoldings or papillary projections into

the lumina of the follicles. In the glands removed from patients who have received iodine previous to operation, the parenchymatous hypertrophy is usually less marked than in the glands from those who have not received iodine. Occasionally additional features, such as thyroiditis, degenerating colloid adenomas, and areas of hemorrhagic degeneration may be found.

The cause of death in uncomplicated cases of exophthalmic goiter is difficult to name. The very common finding of an enlarged thymus and hyperplastic lymphoid tissue, which have been invoked as an explanation of a predisposition to sudden death from obscure reasons, seems to be more likely a result rather than a causative factor of the disease.

There is no known method to prevent the occurrence of *exophthalmic goiter*.

The aim of treatment of exophthalmic goiter should be the reduction of activity of the thyroid gland to a degree that will permit the function of the body and its organs to return to as nearly normal as possible. This occasionally can be achieved by medical methods, although in most cases a portion of the gland should be removed.

In cases of short duration, with a mild degree of activity, rest and Lugol's solution (compound solution of iodine) may be employed under the guidance of frequent and regular determinations of the basal metabolic rate. Activities should be restricted and excitement and overfatigue avoided. From 5 to 10 drops of Lugol's compound solution of iodine should be given three times daily. This regimen must be continued for several months, and in some cases for years. The diet should be the same as that for a healthy, active child, only it should be more liberal in amount.

In cases in which marked cardiac decompensation associated with edema is present, digitalis can be used to good effect. One c.c. of the standardized tincture may be administered daily, but the administration should be discontinued for a week or ten days before surgical measures are carried out.

The use of sedative drugs is seldom if ever indicated, in view of the striking effect of iodine on the nervous phenomena.

In a considerable number of cases the use of the roentgen rays or radium for children was followed by no improvement

and in some, the condition of the children became worse, although subsequently surgical intervention was productive of marked benefit.

Following a preparatory period of two to four weeks, during which 10 drops of compound solution of iodine is given three times a day, resection of the greater portion of both lobes of the thyroid gland can be carried out with a high degree of safety. The improvement which follows this procedure usually amounts to a cure. Administration of iodine is to be continued throughout the postoperative course, and sometimes for months or years following operation. Postoperative myxedema, which is rare in children, necessitates the administration of desiccated thyroid. We have not encountered postoperative parathyroid insufficiency in any children in the Clinic series of patients.

#### HYPOTHYROIDISM

**Cretinism.**—Insufficient thyroid secretion may be manifested in children as athyreotic cretinism, endemic cretinism or myxedema. The term "athyreotic cretinism" is used here to designate the condition resulting from partial or complete failure of development of a functioning thyroid gland in the fetus during intra-uterine life. Synonymous terms are "sporadic cretinism" and "athyreosis." The term "endemic cretinism" is employed to designate a congenital hypothyroid state in an individual born of parents from so-called "endemic goitrous districts," and one or both of whom suffer from congenital insufficiency of thyroid secretion. Synonymous terms are "congenital cretinism," "congenital myxedema" and "congenital hypothyroidism." The chief points of distinction are: (1) in athyreotic cretinism the patient does not suffer from lack of thyroid secretion before birth, whereas in endemic cretinism, patients are deprived of sufficient secretion probably throughout their entire intra-uterine life, and (2) athyreotic cretins are born of normal parents, but endemic cretinism results from hereditary thyroid insufficiency. As endemic cretinism is rare in this country, this discussion will be limited to athyreotic cretinism as it occurs in this country, and for the sake of brevity the term "cretin" will be used to indicate an athyreotic cretin as opposed to one suffering from endemic cretinism.

Although the condition is congenital its recognition may be delayed until the child is several weeks or months old. Failure of development of the thyroid gland occurs in spite of the fact that the parents are free from disease of the thyroid. Contrary to the situation regarding endemic cretinism, there is no proof that lack of iodine in the diet of the mother is responsible for the occurrence of athyreotic cretinism.

Cretinism is caused by lack of thyroid secretion. Since the infant is protected by the maternal thyroid secretion, it does not suffer from this lack of secretion during intra-uterine life, and therefore it appears normal at birth. The patient who has endemic cretinism, on the other hand, shows the effects of intra-uterine deprivation of maternal thyroid secretion.

Following birth, insufficiency of thyroid secretion becomes manifest at the age of a few weeks. The infant, although normal in size at birth, fails to grow at the usual rate. The body remains short and appears well nourished. The extremities are short and pudgy, the face is round, and the features are coarse and heavy.

The skin is dry, thick, wrinkled and cool. The skin over the forehead is wrinkled transversely and gives the appearance of redundancy. The hair is sparse, coarse, dry and brittle. The eyebrows are scanty or absent. The complexion is pasty. The eyes are dull, and the expression is sleepy and apathetic. The base of the nose is broad, the nostrils are large and patent, the lips and tongue thick, the latter often partly protruding. Drooling is excessive. The tissues of the lids and face are full and thick, suggesting edema. The chin is short and recessive. The ears project unduly from the sides of the head.

The neck is short and broad and the head is maintained in poor position. The thyroid gland is usually not palpable. Rarely, thyroid enlargement is present. In endemic cretinism, on the other hand, goiter is almost a constant finding.

The chest and abdomen are short, thick and heavy. The musculature of the abdominal wall is relaxed, the abdomen is protuberant and an umbilical hernia is almost invariably present. When the child is in the erect position, marked lordosis is evident. Above the clavicles are the thickened "myxedematous pads" which fill the angles between the neck and supraclavicular region. The extremities are short, the hands

are spatulous and thick. The external genitalia remain infantile, and in the male the testes are frequently undescended.

Roentgenographic examination of the skeleton is an aid in diagnosis. The cartilaginous condition of the growing portion of the bones persists beyond the usual length of time. The fontanels and sutures of the cranium fail to close. Dentition and the shedding of deciduous teeth are delayed. Centers of ossification are tardy in developing, or fail to develop. Unusual delay in the appearance of centers of ossification of the carpal bones frequently indicates a lack of thyroid secretion.

The infant with cretinism is usually quiet and inactive. The appetite is poor. The speed of tendon reflexes is reduced: the knee jerk may appear active, but return of the leg to the position present before elicitation of the jerk is characteristically slow.

Physical and mental development are markedly retarded. The special senses give evidence of decreased acuity. The ability to sit erect, to walk, and to talk is slow to appear. The gait is wobbling. Speech is slow, inarticulate, and guttural, and the vocabulary is limited. Control of the bowels and bladder develops late, or not at all. Mental progress is practically nil, so that the ultimate status is one of idiocy.

All of the physiologic processes of the body are depressed. The temperature is subnormal; the pulse and respiration are slow. The intake of food and fluid is small, and the output of waste products is decreased. Constipation is marked. Albuminuria and cylindruria are commonly noted. Secondary sexual changes fail to take place. The blood picture is comparable to that found in infants. There is a leukopenia and relative lymphocytosis. The basal metabolic rate is greatly reduced, usually to  $-40$ , or even lower. Hypoglycemia and increased glucose tolerance are usually present. The blood cholesterol may be elevated.

The thyroid gland in cretinism is atrophic or absent. The finding of round-cell infiltration in the aplastic gland of cretins has been accepted by some investigators as evidence of fetal thyroiditis.

Early recognition is of paramount importance, since the longer the delay before treatment, the more extensive become the permanent and irreparable changes. In infants particu-

larly, the condition is likely to be erroneously diagnosed. Mongolian idiocy is frequently miscalled "cretinism," but the mongol is active and more interested in his surroundings, and the condition, unlike cretinism, is evident at birth. Infantile cerebral palsy can be distinguished from cretinism by a history of trauma or infection, by the marked muscular incoördination, spasticity, and irritable central nervous system. Physical and mental retardation of all types can be readily distinguished from cretinism by a therapeutic test with thyroid substance, which if properly carried out, will result in no harm.

The outlook in cretinism depends on the age at which treatment is inaugurated, and the thoroughness and continuity with which it is carried out. Although physical growth and development may attain that of the average child, mental development tends to lag, and only in the cases in which treatment is begun early can the mentality be expected to parallel an apparently normal physical status.

Untreated cretins or cretins for whom treatment is greatly delayed, develop the characteristics enumerated in the foregoing, and even if belated treatment is given them, they remain markedly retarded both physically and mentally. The mental state of such individuals is that of idiocy, and they become subjects for institutional care.

The first essential for proper treatment is to be certain that the thyroid preparation to be used is potent, and the potency must be relatively constant. Cretins have been treated for months and even years with preparations of thyroid which were capable of exerting little, if any, beneficial effect.

Adequate dosage must be determined for each child. For infants and young children whose basal metabolic rates can be obtained only with great difficulty, the condition of the child must serve in most instances as a guide. The rapid improvement during the first week or two of administration of thyroid extract may be followed by evidences of overdosage, such as irritability, tachycardia, continuous loss of weight, diarrhea and sweating. The appearance of such phenomena is an indication for reduction in the amount of thyroid extract given. A return of even mild degrees of previously existing signs warrants an increase to an amount that is somewhat less than that

of the original dose. As growth progresses, slight increases of  $\frac{1}{8}$  to  $\frac{1}{4}$  grain (0.008 to 0.016 gm.) may be made.

The requirement for thyroid extract varies. As a rule, from  $\frac{1}{2}$  grain to 2 grains (from 0.032 to 0.12 gm.) of desiccated thyroid, as marketed by the dependable pharmaceutical houses, will suffice to maintain the metabolism at, or near, normal. Larger and frequent changes in the dose should be avoided, and in no instance should the treatment be completely eliminated.

In all the cases encountered at the Clinic, one standard preparation of desiccated thyroid has been used, and for this preparation, on the average,  $\frac{1}{4}$  grain (0.016 gm.) daily has been found about the proper amount for infants,  $\frac{1}{2}$  grain (0.032 gm.) daily for children between one and three years of age,  $\frac{3}{4}$  to 1 grain (0.05 to 0.065 gm.) for children between three and five years of age, whereas older children and adults are usually maintained on 1 to 2 grains (0.065 to 0.12 gm.) a day. Children often appear to need slightly more in proportion to their size than adults.

**Myxedema.**—Myxedema in infancy and childhood is a disease dependent on a decrease in amount of thyroid secretion, which begins after birth.

The terms "infantile," "childhood" and "juvenile," as applied to myxedema, indicate the period of childhood at which the decrease in thyroid secretion begins. It is implied that a child in whom myxedema develops has been normal for months or years before the onset of trouble, thus differing from cretinism in which thyroid deficiency is present at, or before, birth. The term "congenital myxedema" is employed by some in a sense equivalent to either "athyreotic cretinism" or "endemic cretinism." Gull's disease (spontaneous myxedema of adults), and "cachexia strumipriva," the term suggested by Kocher to designate the condition which follows complete removal of the thyroid gland, have been thought of as applying to adults only, although both spontaneous (idiopathic) and postoperative myxedema occur among children.

Infection and trauma have been ascribed rôles in the production of myxedema of children. In some cases the onset occurs after a febrile illness. Operative procedures on the thyroid gland occasionally result in myxedema of children. In

most cases of myxedema of infants and children, the factor or factors responsible for degeneration and suppression of function of the thyroid gland are not known.

The condition is relatively rare among children. It may occur at any period of childhood, and is said to be more frequent among girls than among boys.

The clinical picture varies considerably, depending on three factors: (1) the age of the child at the time of onset; (2) the duration, and (3) whether or not the remnants of the thyroid gland can still produce and give off traces of thyroxin. The onset is usually gradual. Attention is called to the condition chiefly because of arrested growth, or because of arrested, or decreased, mental development. In general, it may be said that in all cases the condition tends to approach that noted in examination of untreated cretins, but cretinism is prevented because of the onset later in life, thus allowing time for more complete development of the various organs of the body. The length of time required to produce the complete picture of myxedema, after complete cessation of thyroid function, is between six and eight weeks. Gradual cessation of function would of course prolong the development of the complete picture.

The child who has myxedema of long standing is of shorter stature than the average. The head is large, the trunk short and thick, the extremities stubby and the hands spatulate.

The face is round and pale, and the complexion pasty. Deposits of nonpitting myxedematous tissue, especially noticeable in the lower lids, impart an appearance frequently mistaken for that of nephritis or nephrosis. The features become coarse, the lips thick and the expression becomes dull. Often these changes are of minor degree only, and although they should be the first indications noted, frequently they are overlooked.

The skin becomes dry, rough and scaly. Myxedematous deposits are characteristically noticeable in the supraclavicular fossæ, the tissues of the face, or in any other part of the body. The hair becomes scanty, the eyebrows and eyelashes may be lost and even alopecia may appear. The child becomes sensitive to cold and prefers warm clothes and warm surroundings.

Bodily movements become slower and incoördinated. Run-

ning and jumping are discontinued, and the child walks or sits quietly more than usual. Interest in play and schoolwork and in the surroundings generally lags. Speech becomes slow and thick, and response to questions is delayed. The voice assumes a lower pitch and becomes hoarse and guttural. The disposition is usually quiet, placid and unexcitable.

The pulse is slow. The body temperature is reduced. The appetite may remain fair or it may decrease to a marked degree. In spite of this, the weight may temporarily increase, on account of the accumulation of subcutaneous myxedematous deposits. A tendency to constipation may appear.

The clinical picture is reflected in the characteristically lowered metabolic rate. This, as a rule, reaches a level of from  $-25$  to  $-35$ , although figures above and below these have been obtained. In cases in which there is complete loss of thyroid function, the level is usually from  $-35$  to  $-40$ .

If the disease has persisted for some time before the child comes under the observation of a physician, a roentgenogram will reveal the characteristic persistence of the cartilaginous synchondroses and delay in ossification. Although less striking than in cretinism, the evidence so elicited may be equally informative. Centers of ossification in the carpal bones may be present in number consistent with the age of the individual, but the lack of full extent of their development indicates arrested growth.

The urine may contain albumin. The phenolsulfonphthalein test may give evidence of decreased renal function. The urinary excretion of nitrogen is low because of low intake of food and the tendency to a positive nitrogen balance as the edema is developing.

Secondary anemia is common. The blood sugar level is elevated. The glucose tolerance often is increased. Values for blood cholesterol usually are elevated.

Difficulties and errors of diagnosis are more common in the less severe cases. Confusion with nephritis has been mentioned. The delayed growth has been ascribed to rickets, achondroplasia, and chondrodystrophy. Designation of cases of infantile myxedema as cases of cretinism constitutes more a confusion of terms than an error in recognizing the underlying disorder. The most frequently made error is the com-

plete overlooking of cases of slowly developing myxedema in older children. Resort to determinations of basal metabolic rate and to roentgenologic study of the growing portions of the skeleton will serve to clear up the diagnosis in doubtful cases.

The outlook for life is usually good. Children who have myxedema live for a long time but are subject to handicaps of varying degrees. A child who suffers from myxedema for any considerable time cannot be restored to a completely normal state, for just as in the case of cretinism, if a major part of the period of life intended for growth is lost, it cannot be replaced. In cases in which mentality has not been interfered with, physical growth can be stimulated, but not to such an extent as to supply average stature by the time maturity is attained. Disappearance of other symptoms is to be expected if the patient is under proper management, but the end-result will be an individual who is less than normal in stature, or below the average of intelligence, or both, unless recognition of the disease is early and treatment is promptly instituted. Severe, untreated myxedema of children who are less than two years of age have much the same outlook as that of untreated cretins, that is, idiocy. On the other hand, if the condition is recognized early and the children are appropriately treated throughout life they should, as a rule, be practically normal in all respects.

The thyroid gland is small, atrophic, and fibrous. The vesical walls may be the seat of round-cell infiltration.

The same principles of treatment are employed as in cretinism. In both conditions one of the first and most important duties of the physician is to explain fully to the parents, and also to the child as soon as he is old enough to understand, the full significance of the disease and that the patient must take a potent thyroid preparation throughout his life. He must be impressed with the fact that he should never miss taking medication even for one day, and must always plan to have on hand an ample supply of the thyroid preparation on which he has been standardized. There is no disease more satisfactory to treat and in which treatment is more certain of success if the proper principles of treatment are followed throughout life.

## INFLAMMATION

Acute inflammation of the thyroid gland is rare. It is possibly more common among children than among adults, probably because the etiologic agents are more often present in the young.

It occurs more frequently among females than among males. As it tends to affect goitrous thyroid glands more often than normal glands, it is obvious that females, with their higher incidence of goiter, would likewise be more frequently subject to acute thyroiditis.

Many, and perhaps most of the diseases of bacterial or protozoal etiology may be accompanied by thyroiditis. Infections by staphylococci, streptococci, *Eberthella typhi* and *Salmonella paratyphi*, pneumococci, *Hæmophilus influenzae* and *Corynebacterium diphtheriae*, as well as filtrable viruses, may give rise to acute thyroiditis. Trauma may play a part. The organisms reach the gland in most cases by way of the blood stream.

In nonsuppurative forms there is a diffuse leukocytic infiltration of the organ, with proliferation and desquamation of the epithelial cells. In the suppurative form, congestion, abscesses, hemorrhage, liquefaction, and even gangrene of a part, or of the whole, of the gland may be found.

The onset is usually rapid, with chills and fever. Pain, which is increased by swallowing, and swelling of the gland, which is firm at first but which becomes soft over regions of suppuration, are the chief features. Dyspnea, cough, alteration of the character of the voice, and tachycardia may be present.

The history of preceding illness, evidence of acute infection such as fever, leukocytosis, and local pain, swelling, and tenderness are the chief features on which the diagnosis rests.

The outlook is uncertain. Mild conditions subside, but in severe cases, in which there is suppuration, the disease may be fatal, or there may be such a widespread destruction of tissue as to result in myxedema.

Application of heat to the region of the gland may serve to prevent spread of infection to surrounding parts. If suppuration occurs, surgical drainage becomes necessary. If myxe-

dema results, treatment by means of thyroid preparations becomes necessary.

**Chronic Thyroiditis.**—The thyroid gland may be involved by miliary tuberculosis and by congenital syphilis. Such cases are interesting from the pathologic standpoint, but constitute little of clinical importance.

Riedel's disease is of very rare occurrence among children. Riedel reported one case in a child, aged four years. It is characterized by a very firm gland which, on section, reveals extensive fibrosis, some evidence of epithelial proliferation, and collections of inflammatory cells of various types. A hard, firm swelling, pain, dyspnea, and dysphagia are the chief symptoms, and are usually interpreted as indicating malignancy. Treatment is surgical.

#### MALIGNANT DISEASES OF THE THYROID

Malignant diseases of the thyroid are not of common occurrence among children (Fig. 41). In the past twenty-five

Fig. 41.—Adenocarcinoma (grade 1) in the thyroid gland of a girl aged seven years. It is not possible to distinguish such a malignant nodule from a benign adenoma without removal and pathologic examination

years only seven cases of malignancy of the thyroid were found among children admitted to the Clinic.

Malignancy in the thyroid may have its onset early or late in childhood. The first manifestation is an irregular, firm swelling of a portion or of the entire thyroid gland or of the adjacent lymph nodes. Dyspnea, more marked on exertion, is the chief subjective complaint. There is little, if any increase in the metabolic rate, but there may be some evidence of hypofunction of the gland. The neoplasms are adenocarcinomas of low degrees of malignancy. All of those seen at the Clinic were graded 1 and 2 according to Broder's system of grading malignant tumors. The diagnosis can be established by examination of a portion of the mass, or of an adjacent lymph node.

The disease is only slowly progressive, and the life expectancy is a matter of years rather than of months.

Surgical removal when possible, and subsequent irradiation with roentgen rays comprise the most satisfactory forms of treatment for these patients.

## TULAREMIA: DIAGNOSIS AND TREATMENT

THOMAS B. MAGATH

---

ALTHOUGH tularemia has been studied as such but little more than a decade, more is known about the causative organism, its transmission, the lesions it produces, the symptoms it causes, and about the prophylaxis, treatment, and incidence of the disease, than practically any other infection.

When the disease was known only in the western states, the difficulties of diagnosis were restricted; but now that it has been reported from every region of the United States, many parts of Canada, and from other continents as well, geographic factors no longer serve to prod the clinician's threshold of suspicion; he may encounter the disease in a patient from any locality.

### DIAGNOSIS

The occupation of the patient is important. If he is one who by the nature of his work must handle wild game, or ride the western or middle-western prairies or farm land, he is more liable to contract tularemia than otherwise; and if he is a hunter who bags and skins his own game, he is also liable to infection. Men are much more often infected than women, but women who clean and cook rabbits and certain other game are also liable to become infected.

Of fundamental importance in the diagnosis of tularemia is the history of contact with one of the susceptible mammals, birds, insects or ticks. While it is by no means certain that all the transmitting agents have been discovered, it is known that the disease is naturally present in the wild rabbit, grouse, coyote, cat, fox, muskrat, squirrel, woodchuck, range sheep, meadow mouse, rats and horned owl. Wilbur and Leser recently reported a case contracted from handling a ringneck pheasant. Insects known to transmit tularemia are the deer

fly (*Chrysops discalis*), the wood ticks (*Dermacentor andersoni*, *Dermacentor variabilis*, and *Dermacentor occidentalis*), the rabbit tick (*Hæmaphysalis leporispalustris*), and the grouse tick (*Hæmaphysalis cinnabarina*). Failing to elicit the history of contact with one of these mammals or birds, as by handling, dressing, cooking, or caring for their pelts or skins, or of being bitten<sup>1</sup> by one of these insects or ticks or by contact with the body juices of such insects, as by slapping the insect and spattering its contents into the eye, one must inquire into the possibility of the patient's having handled cultures of the organism or experimented with animals inoculated with *Pasteurella tularensis*.

The history of contact with a valid source of infection is so important that the possibility must be thoroughly explored and, failing to obtain a positive history, the probability of tularemia must be only remotely considered.

**The Lesions.**—The time of the appearance of the local lesion after exposure is significant and, as a rule, is from one to four days, rarely as long as twelve days. A limited group of cases have been reported in which no local lesion occurred and these, for the most part, have been among laboratory workers. Although, experimentally, the organism can be made to invade the body through the unabraded skin, it has been suggested that the so-called typhoidal type of tularemia occurs as a result of accidental ingestion or insufflation of the organism. Occasionally one may swallow a tick and, if infected, it might conceivably cause the disease.

The location of the lesion is most frequently on the hands or arms, but lesions of the eye are by no means uncommon. If the disease is acquired from ticks, the location of the initial lesion might be any place on the body, but it is most often on the lower extremities.

The lesion begins as a papule, and by necrosis an ulcer forms during the second week. Such ulcers are of the punched-out type with diffuse necrosis, polymorphonuclear cell infiltration and nuclear fragmentation; the ulcers break down early and drain. There is an early (often in forty-eight hours) lymphangitis and lymphadenitis, affecting the regional lymph

<sup>1</sup>Some have suggested the bacteria are transmitted by the feces of the tick and not by its bite.

nodes. These are tender and painful and usually proceed rapidly to suppuration.

The general symptoms, which begin abruptly, are like those of any other severe infection. The fever curve shows an abrupt rise, often to  $103^{\circ}$  or  $104^{\circ}$  F., and remains at a high level with but slight fluctuations. There are often distinct periods of remission followed by recurrence of the fever. After two weeks or a month of such bouts the fever usually subsides, but the symptoms of fatigue and even prostration continue for some time, even for a year.

Not uncommonly one observes physical and subjective signs of bronchitis, bronchopneumonia or even pleural effusion, and indeed these may be very prominent. In certain cases in which no local lesion is found the whole course may be one of bronchopneumonia. In some cases without local lesions the disease simulates typhoid fever, and in any particular case leukocytosis, enlargement of the spleen and skin lesions, such as macules, papules, vesicles and pustules, may occur.

#### LABORATORY FINDINGS

The laboratory investigation of tularemia is of paramount importance. If the patient is observed during the first two weeks of the infection, one may be successful in isolating the organisms from the lesion either by culturing on cystine agar, as recommended by Frances, or by modification of this medium, as proposed by Rhamy and by Foshay. The organism may also be isolated from a draining lymph node or from the blood stream. One is more likely to succeed if a guinea-pig is first inoculated with the material to be tested. Within five or six days the animal will show the typical lesions, from which *Pasteurella tularensis* can be readily obtained if the organism is present in the material. *Pasteurella tularensis* is a gram-negative, nonmotile, pleomorphic bacillus, growing scantily as a rule. It ferments glucose and glycerol, and most strains ferment mannose, levulose and maltose. In the presence of these sugars, acid is first produced, then alkali. Hydrogen sulfide is produced by its action on cystine.

**Skin Test.**—A skin test developed by Foshay is reported to be very useful and reliable in the early diagnosis of the disease, in fact, as early as the third day after infection. The

antigen is prepared by killing and treating a suspension of bacteria with 1 per cent formaldehyde for twenty-four hours, then treating it with hydrogen peroxide for forty-eight hours, followed by 1 per cent sodium ricinoleate in distilled water for twenty-four hours. The preparation may be made by treating organisms with nitrous acid for twenty-four hours, then suspending them in 1 per cent sodium ricinoleate and treating with 0.5 per cent phenol. If the disease is of recent origin, a test is made by injecting a small amount of antigen intracutaneously, enough to make a wheal 2 mm. in diameter; if the disease has been present for some time, enough antigen is injected to make a wheal 4 mm. in diameter. When read at forty-eight hours, a positive reaction has an erythematous wheal 5 to 6 cm. in diameter, with a hard indurated center about 1 cm. in diameter. The reaction lasts five days and a brown patch remains for several weeks. The test will be positive at least as long as five years after infection; it must be interpreted, therefore, in light of the patient's symptoms.

**Agglutination Test.**—After the patient has suffered from the disease about two weeks, the blood serum exhibits both a positive complement-fixation reaction and a positive agglutination test.

The complement-fixation test is performed along standard lines using as antigen a suitable suspension of the organism. The test is of scientific interest, but on account of its complexity it is not recommended for routine use. Of greater practicality, the agglutination test is to be preferred. A suitable, killed suspension of the organism is treated with varying dilutions of the patient's serum and the reading is made after incubation. At first the titer is low, 1:40 to 1:80, but it rises rapidly and, by the third week, it is usually quite high, even as high as 1:5,000. The reaction persists for months or even years. A rising titer is perhaps the most perfect corroborating test, next to actual isolation of the organism from the lesion, a very much more difficult task. In cases without a local lesion or exact history of exposure, especially when the chief findings are in the chest, a rising titer in the agglutination test may be the chief basis for establishing a diagnosis.

If one must make the diagnosis at necropsy, it must rest on the finding of typical lesions in the lung, liver and spleen.

miliary necrotic areas, essentially caseous. The lesions in the lungs are characterized by thrombosis of small arterioles with necrosis, and surrounding mononuclear cell infiltration. One may isolate the organism from the lesions; or better, inoculate a guinea-pig with the material. It may be possible to obtain enough serum with which to perform an agglutination test.

### TREATMENT

**Prophylaxis.**—One may fairly successfully avoid the disease by handling no susceptible animals and by avoiding ticks and deer flies. In dressing game, rubber gloves should be worn, and sick wild rabbits, squirrels and mice should be avoided. Certainly after handling any of these animals the hands should be carefully scrubbed with soap and water and washed in an antiseptic solution. If one has received scratches or wounds while handling susceptible animals, the wound should be treated by thorough washing and application of a good antiseptic.

Foshay has advocated immunizing laboratory workers and those engaged in the wild rabbit industry with a detoxified vaccine he has developed, but as yet no extensive use of it has been reported.

**Active Treatment.**—Aside from general supportive measures and surgical drainage of liquefied lymph nodes, there is no particular remedy to advise except certain specific procedures.

In a limited number of cases, two having been reported by Baer, the local lesion has been treated with roentgen rays. Both of Baer's patients were treated before the fourth day; one had lymphadenitis but the other did not, and a positive agglutination test developed in both cases, although at first it was negative. The patients were treated with one-half unit (erythema) of unfiltered roentgen rays applied to the lesion and both showed marked improvement the next day. The disease was apparently aborted.

After the disease has advanced, various forms of treatment have been suggested. Fisher reported treating three patients with neoarsphenamine, although the first case was diagnosed on the basis of the history and clinical manifestations only. Three doses, 0.45 gm., 0.6 gm., and 0.75 gm., were given at five-day intervals. He reported that all the patients were well

after the third dose. Some isolated instances of beneficial results following the use of certain dyes have been reported, but these reports and the lack of confirmation leave one doubtful as to the value of such remedies.

**Foshay's Serum.**—The greatest progress in treatment has been made by Foshay. He has immunized goats and horses over long periods of time with detoxified antigens of *Pasteurella tularensis*. The serum is obtained and administered intravenously, usually in two doses of 15 c.c. each on successive days. In cases in which the lymph nodes are greatly involved, a third dose is indicated. It should be given as early as possible and with the usual precautions against reactions. Improvement is usually noted on the third day. He has reported on 240 cases treated with striking effects. The duration of fever was not shortened, being 26.44 days on the average. The duration of adenopathy was lessened by nearly half, or to 2.41 months. The duration of the disease and the disability due to it was shortened to 2.78 months, or about half the time of untreated cases, and the freedom from subjective symptoms was effected almost immediately. The mortality was reduced to about a third the usual mortality of 6 to 8 per cent.

The best and most striking results are obtained when patients are treated during the first three weeks and, after eight weeks, it is questionable whether the risk of serum treatment and the uncertain benefit to be gained justify its use.

Sharp and Dohme have placed on the market a serum made after the manner of Foshay, and Flinn reported favorably on its use in two cases. One patient was given 30 c.c., the other 90 c.c., followed by 30 c.c. of Foshay's immune goat serum. Since these are the only reports available, one must reserve opinion on the commercial product until more cases are reported. It would be advisable to develop some means of concentrating the serum, as has been done with better known immune serums.

It can be seen that specific treatment of tularemia is still somewhat in an experimental stage, but the brilliant results which have attended work on this interesting infection foreshadow a solution to the problem of treatment in the not too distant future.

## CUTANEOUS MANIFESTATIONS OF SYSTEMIC DISEASE

LOUIS A. BRUNSTING

---

A THOROUGH understanding of the structure and functions of the skin is essential to an appreciation of the rôle of this organ in general bodily economy. It is taken for granted that the skin serves as a protective outer coat, but aside from this it is not only the largest, but one of the most vital organs of the entire body. Like the liver, the skin can repair itself to a certain point, but when one-half to two-thirds of its surface is destroyed, as in the case of extensive burns, for example, life is impossible.

Dirt, bacteria and water do not penetrate the unbroken skin by virtue of the protection afforded by the waxy, sulphurous keratin of the stratum corneum. This material multiplies itself in response to friction and furthermore serves as a buffer against undue exposure to ultraviolet light. The pigment of the skin, found in the basal cells of the epidermis and in the chromatophores of the upper cutis, is laid down in response to certain external stimuli, such as light, heat and friction, but it is controlled from within the body through a chemical and nervous mechanism which is little understood.

The several layers of the skin, including the fat, serve as a blanket to check the loss of bodily heat by radiation. On the other hand, the dilatation or constriction of the superficial capillaries and the evaporation of sweat are important factors as well in temperature control. No small amount of sodium chloride is excreted in the sweat in prolonged febrile bouts such as in malaria, pneumonia or artificial hyperpyrexia.

The subcutaneous tissues serve as a spongy reservoir for the storage of water and excess nourishment in the form of glucose, and these are held until they are needed elsewhere.

The reticulo-endothelial system in the skin is significantly associated with immunologic phenomena, tests for susceptibility to tuberculosis, scarlet fever, diphtheria, tularemia, lymphogranuloma inguinale and fungous infections being interpreted by intracutaneous tests. Likewise, the skin is a shock tissue in certain anaphylactic phenomena, and tests for protein sensitization in asthma, hay fever, eczema, and so forth, utilize the urticarial reacting mechanism of the skin.

Undoubtedly the skin is the medium which adapts the vitamins activated by the sun to the use of the body, perhaps by means of active irradiation of sterols in the epidermis; the exact mechanism of this process of transfer, however, is not known.

Disorders of the skin comprise too complex a subject to be adequately discussed except in a textbook. There are common diseases which are entirely limited to the skin alone, such as moles and new growths (both benign and malignant), parasites, and infections by fungi and other microorganisms; and there are lesions which appear on the skin but are really the expression of an underlying constitutional disturbance, such as tuberculosis, syphilis, or lymphoblastoma. In this latter sense the skin may be thought of as a mirror that reflects the state of the general health of the body. The study of the skin and its disorders from this point of view is the intriguing feature of the science of modern dermatology.

#### DISORDERS OF PIGMENTATION

**Addison's Disease.**—The cardinal symptoms of Addison's disease are asthenia and a gradual decline in general weight and strength associated with a uniformly low value for the systolic blood pressure and, in most instances, a generalized pigmentation of the skin which is especially pronounced in the folds of the body, the axillæ, and in the genital and perianal regions. The skin assumes a soft, smooth texture. Hyperpigmentation is the rule, although it may be absent. Usually the mucous membranes are involved as well as the skin. Microscopically there is simply an increase in the amount of pigment in the basal cells and chromatophores where it is ordinarily found. In Addison's disease it happens rather frequently that

pigmentation of the skin is the first sign of the syndrome which calls attention to the correct diagnosis.

**Acanthosis Nigricans.**—This is a rare disease which affects juveniles as well as adults. I am concerned here only with the latter type. Examination of the patient reveals hyperpigmentation of the same sites as those that are involved in Addison's disease, namely, the axillæ and the genital folds most of all, although there is also a permanent exaggerated wrinkling of the skin in these sites which is quite characteristic. One may find small papillomas on the skin of these regions or along the sides of the neck. The microscopic picture is quite distinctive: There is an increased thickness of the stratum corneum, but the most important change is in the prickle-cell layer, where there is a marked amount of irregular acanthosis with adjacent areas of thinning of the skin almost to the point of atrophy. Pigmentation is irregular and is particularly prominent below the zones of acanthosis. The clinical importance of the cutaneous picture of acanthosis nigricans in almost all the cases in which adults are affected is its association with abdominal or pelvic malignancy. Apparently the changes in the skin are secondary to some involvement of the chromaffin-sympathetic system.

**Hemochromatosis.**—Pigmentation in this condition is characterized by diffuse bronzing of the skin, from which it gets the name "bronze diabetes," because there is usually an associated diabetes or some obscure disorder of the liver such as cirrhosis. The demonstration of this iron-containing pigment in the skin by selective staining is usually sufficient to make the diagnosis. It happens most often that biopsy of the skin is necessary in order to settle a puzzling diagnosis in regard to visceral disturbance, the discoloration of the skin rarely being sufficiently diagnostic in itself.

**Other Disorders of Pigmentation.**—The foregoing conditions must be distinguished from certain other disorders which are characterized by pigmentation of the skin. Chronic arsenism resulting from a reaction to the pentavalent and inorganic arsenical preparations, such as potassium arsenite (Fowler's solution), is quite distinctive clinically and histologically. Over the trunk there is a mottled appearance of alternating hyperpigmentation and depigmentation which gives

a raindrop effect. In the same individual one may frequently find discrete hyperkeratoses of the palms and soles which may terminate in malignant degeneration.

Diffusely generalized hyperpigmentation is seen in argyrosis, but the color is more blue-gray than brown and pigmentation is usually a consequence of the ingestion of silver compounds, or their medical use on mucous membranes over a prolonged period. Microscopically, the glistening particles of silver are best demonstrated by dark-field illumination in a lightly stained section where they will be found chiefly in the propria of the sweat glands and in the region of the blood vessels. The use of silver nitrate was formerly in vogue in the treatment of peptic ulcer; today it is only rarely used for this purpose.

In some cases of Hodgkin's disease diffuse hyperpigmentation of the entire skin may occur without other objective evidence of the disease being present. Now and then one sees examples of this condition wherein the pigment is limited to zones or bands along the forehead or on the trunk. Following exfoliative dermatitis from several causes the skin is usually hyperpigmented for many months. In cases of scleroderma of the diffuse type one frequently sees a most intense darkening of the skin, which may be generalized. In women during pregnancy or during the menopause or in the course of thyroid or ovarian disease there may be localized or generalized increases and decreases in pigmentation. The yellowish appearance of the skin in cases of pernicious anemia is well known, as is the chamois color of the xanthomatous individual in whose blood and tissues there is an excess of lipoids. An excess of carotene in the blood resulting from the overuse of oranges, carrots, or certain green vegetables in the diet often stains the skin yellow, which coloration can be detected particularly on the palms and soles. In polycythemia vera the face, neck, and extremities are tinged from dusky purple to brick red. The presence of disease in the gallbladder or liver may first become manifest when the skin and sclera become tinted with bile pigments, producing jaundice. Other discolorations of the skin characterized by hyperpigmentation are familiar to dermatologists, and many of such conditions are the result of local irritation in the skin itself, resulting from infestation with parasites, or neurotic excoriations and so forth, and they must

be differentiated from the foregoing conditions which have to do with systemic disease.

### PRURITUS

No one has satisfactorily explained the symptom of pruritus or the mechanism by which it appears as the presenting symptom of underlying systemic disease. Like pain, pruritus is subjective and varies tremendously among individuals, and on various occasions in the same individual. The most common clinical entity with which pruritus appears is jaundice. Few patients who have had complete biliary obstruction from stricture or neoplasm fail to have some degree of pruritus in association with other symptoms. It frequently happens that pruritus is the earliest symptom before the skin and the sclera become tinted and, in fact, there may be itching of the skin in association with disease of the liver and gallbladder without any elevation of the serum bilirubin or any clinical evidence of jaundice.

Pruritus is usually most intense in urticaria, and it may occur in dermatographism without the presence of wheals. Elderly individuals whose skin and accessory structures are undergoing natural involution sometimes have an intractable pruritus without apparent cause. When this condition affects elderly men, a search should always be made for a disorder of the urinary tract, such as urinary retention from enlargement of the prostate gland with resulting accumulation of excessive amounts of nonprotein nitrogen in the blood. Urticaria is sometimes the first symptom of hyperthyroidism. In diseases such as the lymphadenoses, pruritus and objective changes in the skin occur in more than a third of the cases. When pruritus exists for a considerable time without objective evidence of disease, a careful search should always be made for enlargement of such lymph nodes as can be palpated or that can be detected in the mediastinum by roentgenograms of the thorax. Smears of the blood may point to changes of Hodgkin's disease, or there may be evidence of one form or other of leukemia. Pruritus is rare in cases of lymphosarcoma unless it is associated in its course with one of the other manifestations of lymphoblastoma. In granuloma fungoides, on the other hand, the disease is frequently preceded by a long period of pruritus and by more

or less eczematoid changes in the skin resembling parapsoriasis. In cases of individuals having a background of allergic disease such as asthma and hay fever one encounters paroxysms of pruritus which may become evident on the skin in the form of urticaria or neurodermatitis. In pregnancy and in diabetes a troublesome pruritus may develop, but it is usually of the localized type and affects particularly the perianal regions and the genitals.

#### ENDOCRINE AND METABOLIC DISTURBANCES AND THEIR RELATION TO THE SKIN

In many disturbances of the endocrine glands, concerning which so much has been written in the past few years, there is often an obscure interrelationship of more than one gland in the so-called "pluriglandular syndrome." The exact pathologic basis of many of these diseases is still unknown, although in some instances typical syndromes have been recognized for centuries. The skin and its accessory structures often partake of the general systemic disturbances, and not infrequently the first signs of the underlying disorder become apparent on examination of the skin.

**Myxedema.**—In this condition there is dryness and scaling of the skin with puffiness of the entire surface of the body which becomes noticeable first of all about the loose skin of the eyelids and face. Secretion of fat and sweat is diminished, the hair becomes coarse and is often lost, and an urticarial eruption may appear. There is a tendency sometimes for excessive amounts of fat to be deposited. Microscopic examination of the skin in cases of myxedema, and in states in which the basal metabolic rate is low but in which no obvious myxedema exists, reveals a chemical change in the subcutaneous tissue which suggests an excessive deposit of mucin. A form of localized myxedema has been described which is characterized by the appearance of nonpitting, edematous, tawny plaques on the lower extremities in association with paradoxical symptoms of acute hyperthyroidism of moderately severe degree. Microscopic examination of this tissue likewise reveals excessive deposits of mucin.

**Hyperthyroidism.**—In cases of exophthalmic goiter, probably particularly because of the excessive heat and moisture,

the skin is soft and thin and dermatographism and urticaria are common. Vitiligo appears more often as a disturbance of pigmentation than does chloasma. The nails may be brittle and the hair becomes sparse. It has been stated that scleroderma is commonly associated with the hyperthyroid state, but this finding does not agree with experience at the Clinic.

### **Disturbances of the Pituitary and Suprarenal Glands.**

—Cushing's syndrome is associated with adenoma of the basophilic cells of the anterior lobe of the pituitary gland, but the clinical features may also appear in association with tumors of the suprarenal cortex, wherein there is no disturbance of the pituitary gland. The disorder almost entirely affects women, and it is characterized first of all by a sudden plethoric obesity in which the fat is deposited on the face, neck, and trunk (especially prominent being the buffalo hump on the upper part of the back), and sparing the extremities. Another of the cardinal symptoms is hirsutism and, in women, this assumes the masculine characteristics. Other phases of the disorder, such as amenorrhea, hypertension and osteoporosis, do not have anything to do with the skin. In those cases in which this syndrome has been seen in association with tumors of the suprarenal cortex, the frequent occurrence of marked oiliness of the skin with acne in the usual sites has been noted, the condition affecting adults who have not previously suffered from acne. The several features of this disorder, namely, the rapidly acquired, peculiarly distributed obesity and hirsutism and the suddenly appearing acne, make one suspicious on inspection of the skin alone of a disturbance associated with the suprarenal cortex or pituitary gland.

Addison's disease, which is also directly referable to a disturbance of the suprarenal glands, has been discussed previously.

**Disturbances of the Pancreas.**—The affections of the skin which occur in association with diabetes mellitus are three: furunculosis, pruritus, and xanthomatosis, and the first two of these are probably directly attributable to the increase in the concentration of sugar in the skin. The appearance of xanthomas in diabetes will be discussed later.

**Disturbances of the Gonads.**—The evidence presented to demonstrate a relationship between disorders of the skin and

disturbances of the gonads is based largely on fancy and conjecture. However, it is quite apparent from casual observation that there is a difference in the texture of the skin of men and women, at the time of puberty, for example, the beard of the male becoming evident. In young women with acne vulgaris there is frequently a pronounced flare of the condition at the time of the menses, and in women in the third decade of life who are frail, asthenic and dysmenorrheic, an intractable type of acne of the chin often develops without the presence of comedones, and affecting this same type of young woman there has been described a rare form of dermatitis which is thought to be associated with dysmenorrhea. During pregnancy one occasionally sees a bullous dermatosis similar to pemphigus or dermatitis herpetiformis, which is known as impetigo herpetiformis. In pregnancy some common skin diseases such as psoriasis may disappear completely, only to reappear in exaggerated form within a short time after parturition. At the climacteric, in association with the disagreeable paresthesias and hot flashes there may appear troublesome pruritus of the vulva, and objective examination is frequently negative except for urticarial edema with neurodermite. This condition most frequently affects women who have had a background of urticaria and migraine, and sometimes eczema of the palms and soles. Skin tests in these cases to demonstrate an element of specific hypersensitivity are fruitless.

**Calcinosis.**—Deposits of calcium appear in the skin as localized plaques or as a part of a systemic process, but their relationship to a disorder of the parathyroid glands is not established.

**Xanthoma.**—This disease develops as a result of disturbed lipid metabolism. It is characterized by the appearance of yellow or chamois-colored papules or nodules which coalesce in masses of varying sizes and which are distributed particularly over the bony prominences of the extremities, and later, on the trunk and face and even on the mucous membranes. Examination of the blood in the more extensive forms of the disease often reveals lipemia, the lipids in the blood sometimes reaching the astounding level of 4,000 to 5,000 mg. per 100 c.c. and the blood serum to the naked eye being a milky liquid. Diabetes mellitus may be present, and occasionally there is

some evidence in the form of dwarfism or acromegaly which suggests an associated disturbance of the pituitary gland. Microscopically the individual lesions are seen to be collections of cells of characteristic structure. These cells are found at first in the neighborhood of the blood vessels and occur as the result of infiltration following resorption of the doubly refractile lipid compounds—cholesterin and the fatty acids. Both the endothelial and connective tissue cells are able to absorb these compounds. Sometimes the entire surface of the skin is tinted a chamois, pale yellow. When a strict dietary regimen is instituted, which consists of limitation of the amount of lipids, and if the diabetes which may be present is brought under control, there often results a surprising involution of the xanthomatous lesions of the skin.

**Amyloid.**—Localized deposits of amyloid may occur in the skin in the form of lichenified plaques on the lower extremities, chiefly of males who show no other disturbance of general disease. "Systematized amyloidosis," on the other hand, is the term which is applied to a rare and fatal disease wherein there is diffuse and nodular involvement of the entire skin, subcutaneous tissue, muscles, tongue, gastro-intestinal submucosa, and the walls of the larger blood vessels of the body. The spleen, kidneys and liver are spared. There is Bence-Jones proteinuria but no definite evidence of multiple myeloma. There are none of the usual causes for amyloidosis in the form of long-standing suppurations, malaria, tuberculosis or syphilis. The condition may first be recognized by the appearance of yellowish papules and nodules about the skin of the eyelids, face, neck and oral mucosa, by the waxy coloration of the skin as a whole, and by the enlargement of the tongue. Amyloid is stained selectively by Congo red dye to a pinkish red, and this affinity may be used as the basis of a test by subcutaneous injection "in vivo" of a 1 per cent solution of the dye in the vicinity of the suspected deposits of amyloid.

**Photosensitization.**—There are certain rare affections of the skin, congenital or acquired, in which there is a hypersensitivity to light of various wave lengths, particularly that in the range of ultraviolet rays. This condition may affect adults who are otherwise normal but who, when exposed to the sun, manifest pronounced urticarial or eczematous reactions; in

children, the condition frequently appears as *hydra vaccini-forme* and is characterized by marked flares in the springtime on first exposure to bright sunlight, although in more advanced cases the trouble may be apparent the year round. In both these conditions there is probably a disturbance of metabolism, as a result of which porphyrin appears in the urine and feces in abnormal amounts. The site of origin and manner of formation of porphyrin is not known definitely, but it is probable that it is an intermediate product between hemoglobin and bile pigment. Hematoporphyrin is a fluorescent substance which occurs in all normal individuals, but under normal conditions it is completely decomposed without producing untoward symptoms.

Xeroderma pigmentosum is a decidedly familial disease which is characterized by hypersensitivity to light, spotted pigmentation of the exposed surfaces of the skin, and presenile aging, with a marked tendency to the development of basal cell epitheliomas. Consanguinity may possibly be a factor in the precipitation of this disorder. In the more advanced cases of xeroderma pigmentosum the affected individuals must be protected at all times from exposure to the direct rays of the sun, either by application of protective creams which filter out specific rays of light, by covering the skin with impermeable clothing, or even by shunning light absolutely.

In certain other conditions of the skin there is a pronounced photosensitivity, namely, in lupus erythematosus, in its more acute forms, and in pellagra. Lupus erythematosus may be decidedly aggravated by exposure to natural or to artificial sunlight, and a patient in the chronic or subacute phase may sometimes suffer wide dissemination of the condition as the result of such exposure. In pellagra, the cutaneous evidences appear together with, or apart from, the other features of the syndrome, that is, the gastro-intestinal symptoms and the more or less dementia. The distribution of the eruption over the face, neck and exposed surfaces of the hands and forearms, and the pronounced recurrence in old cases during the spring and summer months, leave little doubt as to the photosensitivity that exists. It is necessary to protect the skin of pellagrins from direct exposure to sunlight for a considerable period even though the general health has been brought to somewhere more near

normal by a diet that is adequate in all respects, particularly as regards the vitamins, especially vitamin B<sub>2</sub>, which is found so abundantly in yeast.

### INFECTIONS

In no other systemic disease does the skin reflect such a large variety of indications of underlying disturbance as in the field of infections. Wile recently summarized this relationship in a discussion of what is known and what is yet unknown about focal infections. Diseases of this type which are definitely related to a primary focus are listed as follows: syphilis, tuberculosis (leprosy), trichophytosis, sporotrichosis, tularemia, blastomycosis of the systemic type, scarlatina and vaccinia. Related diseases probably are: erythema multiforme, and possibly dermatitis herpetiformis and alopecia areata. Those diseases in which the primary site is presumptive or probably in which the secondary manifestations on the skin are due to a toxin rather than to an actual dissemination of the organisms, are herpes zoster, many of the multiforme erythemas, some types of urticaria, and a few unusual "toxic" tuberculids.

In syphilis so much emphasis has been placed on the manifestations of the disease as they appear on the skin that there has been a corresponding lack of emphasis on syphilis as a systemic disease. Fortunately, with the modern methods of teaching the subject in the medical schools, with improvement of facilities for investigation of the cardiovascular and nervous systems and with the more thorough follow-up of old cases of proved syphilis, the disease has gradually outgrown the limited province of the urologist or dermatologist. The study of syphilis, of course, is a province within itself and requires first of all a thorough foundation in internal medicine. Textbook descriptions of the chancre and the secondary manifestations of syphilis are matters of common knowledge. Nevertheless it is difficult to rid the profession of the notion that all patients with syphilis must pass through these recognizable early phases. In our experience at the Clinic, in dealing with patients who are found to have latent syphilis or involvement of the cardiovascular or nervous systems, about 60 per cent of women and 40 per cent of men frankly confess ignorance of the early signs of the disease. Unrecognized, late cutaneous syphilis is be-

coming increasingly rarer with the increased threshold of suspicion for syphilis in general and the ready availability of the various specific remedies that will in most instances rapidly heal such lesions.

In a recent report on the relationship of tuberculosis to the tuberculodermas, Michelson emphasized the fact that tuberculosis of the skin is, after all, tuberculosis, and that in many instances the cutaneous signs are manifestations of an internal infection. The various types of morphologic classification serve their purpose in reflecting the grade or degree of allergy of the particular individual, but these distinctions should not divert one from the study of the relationship of the patient to the whole disease.

In the field of fungous infections it is not uncommon to see a widespread allergic reaction on the skin explained by a focal kerion; or, as has been more recently emphasized, the vesicular dyshidrotic type of eruption of the hands which follows infection of the feet with epidermophyton. In the group of focal diseases which are presumed to be due to streptococci, erythema nodosum is the outstanding example. This condition is characterized by fever and rheumatoid symptoms and by the appearance of bright red, indurated, painful nodules, usually on the lower extremities but sometimes elsewhere. The primary site of the focus is thought to be in the tonsils or teeth; but this view has not yet gained complete acceptance. Wile pointed out the difficulty of relating the cutaneous syndrome to a primary site of infection in some of the borderline conditions. This is especially true in such conditions as the exanthemas and in keratoderma blenorrhagica in which there are crusted cutaneous lesions and arthropathy in the course of systemic infection with the gonococcus.

An unusual type of extensive sloughing ulceration of the skin has been described as pyoderma gangrenosum, and it occurs in association with fever and arthritis in individuals who were debilitated as a result of some infectious process elsewhere in the body, mostly chronic ulcerative colitis. A striking parallelism was demonstrated between the degree of activity of the cutaneous lesions and the major infectious focus, and healing of the ulcers was dependent on the successful treatment of the systemic disease.

**Lymphoblastoma.**—Montgomery in a recent comprehensive summary of the cutaneous changes in the puzzling group of diseases associated with lymphoblastoma, has added emphasis to the assertion of Keim and of Wile of the striking interrelationship from a clinical and pathologic standpoint between leukemia, lymphosarcoma, Hodgkin's disease, and even granuloma fungoides. It is not my purpose here to discuss the points of controversy that arise in connection with these interrelationships. In our experience at the Clinic, taking the lymphoblastomas as a group there are cutaneous signs or symptoms of one form or another in probably a third of the cases, and in many instances these are the primary symptoms of the disease.

Granuloma fungoides is essentially a chronic disorder, although it may appear in a fulminating *d'emblée* type. It is characterized by the appearance on the skin of nodules or tumors of varying sizes which in some instances change naturally or under the influence of treatment over a period of many years. Pruritus is usually intense. In some cases before the nodules and tumors become evident there is widespread scaling of the skin with pruritus which cannot be distinguished from parapsoriasis en plaque. The histologic changes consist chiefly of infiltration of the cutis in which there is a multiplicity of cellular types together with pyknosis and karyorrhexis of the individual cells and the tendency to clumping of the endothelial or reticulum cells to form pseudo-giant cells.

In Hodgkin's disease one may recognize specific and non-specific lesions on the skin. There may be nodules with the typical architecture of the pathologic condition seen in the lymph nodes, or the skin may show a nonspecific infiltrate which is the result of an inflammatory reaction following excoriations from scratching incidental to pruritus. There may be widespread urticarial lesions, and later, a superficial scaling with the development of generalized erythroderma. In this event the microscopic picture of the skin is only rarely that of true Hodgkin's disease and the diagnosis must be made on the basis of the general examination of the patient in regard to enlarged lymph nodes, fever, and so forth, or on the basis of biopsy of one of the lymph nodes. Changes in the skin occur with sufficient regularity in Hodgkin's disease to warrant suspicion of this diagnosis whenever there is an unexplained pruritus in

association with enlargement of the lymph nodes. Sometimes there is a pronounced amount of pigmentation of unusual distribution, which has been mentioned before. Herpes zoster, and an unusual herpes simplex of severe degree, may be seen as incidental features of the disease or as the result of direct infiltration of nerve ganglions.

Of the leukemias, the myelogenous type is rare. In this connection there may be tumors of varying size on the skin or disruptions of the vascular network manifested by hemorrhages and purpura. In lymphatic leukemia the skin is frequently infiltrated with masses of the typical round cells and biopsy is quite distinctive. Circumscribed plaques or diffuse scaling erythroderma may be present. One peculiar case comes to mind of a woman whose diffuse solid edema was limited to the face and neck; this was the chief symptom of the disorder. Examination of the blood smears and biopsy of the skin revealed typical evidence of lymphatic leukemia, and there was prompt, although temporary, response to treatment by roentgen irradiation. We have seen at the Clinic, and there have been recorded in the literature, numerous examples of transitions from one phase of these conditions to another; that is, at one time the blood picture will be that of leukemia, the section of a lymph node may reveal Hodgkin's disease, and there may be fatal termination with postmortem findings of lymphosarcoma.

In lymphosarcoma there may be nodules on the skin as well as enlargement of the lymph nodes. In some cases purpura, ecchymosis and blebs appear, and in others, extensive ulcerations. In lymphosarcoma as well as in true leukemia the symptom of pruritus is less common than in granuloma fungoides and Hodgkin's disease.

It is helpful, until more is known in regard to the etiology and interrelationship of this obscure group of conditions, to maintain them as distinct entities and to record particularly those instances wherein an interrelationship is manifested. The lymphoblastomas represent one of the most unusual types of systemic disease in which the cutaneous signs are frequently pathognomonic and even may be primary manifestations of a lymphoblastoma.

## LATENT SYPHILIS AND ITS TREATMENT

PAUL A. O'LEARY

---

"LATENT SYPHILIS" is a term which has steadily gained in popularity since the old idea that syphilis manifested itself in three stages only has been found to be no longer tenable. There are many reasons why subdivision of the course of syphilis into the acute, latent, and late phases has a more significant meaning than the former classification of first, second, and third stages. The latter nomenclature recognized only the acute and the late periods of the disease and completely ignored that phase which is now called "latency."

It is now readily accepted that many patients pass through the acute phase of syphilis quickly, sometimes with lesions of the skin and mucous membranes which are quite insignificant. That these manifestations of the early form of the infection are sometimes so mild as to attract no attention on the part of the patient is evidenced by the occasional case which will pass unnoticed through the hands of several medical examiners until the flocculation test is found to be positive. These cases are seen often enough in a dermatologic clinic to emphasize the point that the patient who has manifestations of late syphilis and denies a knowledge of ever having had the acute manifestations may not be falsifying; it may have been that the acute signs of the disease were so transient that they passed unnoticed.

It is likewise now recognized that all patients who acquire syphilis do not have a chancre or the clinically recognizable lesions of the skin or mucous membranes that were formerly called "secondaries." The disease in these cases quickly passes into the period of latency and only a positive flocculation test gives evidence of the infection; or the patients may be unfortunate enough to show rapid development of one or more of the late sequelæ of the disease.

Latency may be defined as that phase of the disease when neither clinical signs nor symptoms of syphilis are present. It may also be thought of as concealed or dormant syphilis. Latent syphilis has been subdivided into the early and late types, those whose latent syphilis is recognized during the first four years of the disease being in the period of early latency, and those whose latent syphilis is recognized after the disease has been present for four years or more being in the period of late latency. The significance of this subdivision will be elaborated on later in this paper. Latent syphilis presents numerous features which make it an important phase of the disease. These various factors will now be discussed in detail:

Latent syphilis is probably next to early syphilis the most frequently encountered form of syphilis. Many patients pass into the latent stage and remain there the remainder of their lives, to die of some intercurrent disease or of old age. Others pass into the latent stage, remain in it for periods of ten years or more and then manifest mild or severe clinical signs of syphilis. A much smaller group of patients never remain in the stage of latency but pass quickly through it, the clinical signs of malignant syphilis developing either in the skin, or viscera, or central nervous system within a year or so after the disease is acquired. Accordingly, it is obvious that latent syphilis is not to be considered as always being a permanent or stationary form of the disease. If, however, the type of latency develops which does remain permanent for the rest of the patient's life, he is most fortunate: in fact, syphilotherapists often strive to produce this type of latency.

Latent syphilis also has been divided into clinical, serologic, and pathologic latency by Moore and his co-workers, and it will be considered briefly under these headings.

Clinical latency exists when no clinical signs or symptoms of syphilis are discernible. This does not imply, however, that syphilitic invasion of the viscera has not occurred, because when the aorta or liver is only slightly involved, signs and symptoms are absent. These manifestations of syphilis may remain slight and the patient may be asymptomatic for years. Accordingly, the line of distinction between clinical latency and asymptomatic visceral syphilis may not be well marked and this at times constitutes a difficult diagnostic problem. Clinically.

latent syphilis may follow one of two courses: it may remain as such for the rest of the patient's life, during which he will remain free of symptoms and signs of syphilis; on the other hand, visceral syphilis may become recognizable after several years of such latency. The important point to bear in mind in regard to the management of syphilis which is latent clinically is that in some of the cases extensive treatment is warranted whereas, in others, only observation and frequent reëxaminations are indicated. In the consideration of the treatment of latent syphilis this point will be discussed in more detail.

Serologic latency implies that, although serologic tests are negative, the patient still has active foci of syphilis. Ten years ago, when the serologic technics were less sensitive than they are at present, serologic latency was very common; however, with the advent of the newer flocculation tests, serologic latency was encountered less frequently, and with the advent of still more sensitive serologic technics which no doubt will be developed in the future, serologic latency will be even less common than it is now.

Pathologic latency means that active *Spirochæta pallida* are present in the tissues, but that a pathologic reaction on the part of the host to the invader, in the form of a minute or massive gumma, is lacking. This conception of latency was advanced by Warthin, who demonstrated *Spirochæta pallida* in the cardiac muscle and testes of patients with latent syphilis in the presence of mild pathologic changes. For many years this was the basis for the conception that latency was characterized by the development of nests of *Spirochæta pallida* which might remain dormant for years or might at any time become active and produce clinically recognizable manifestations of syphilis. The proof that the state of pathologic latency exists is dependent on the findings at necropsy, and this is a pathologic problem which is still subject to debate.

A diagnosis of latent syphilis is made possible by recognition of the status of the patient as conforming to the following criteria:

1. If a history of acute syphilis is elicited, the disease may be classified as early latency if it is of less than four years' duration, or as late latency if it is of longer duration.
2. The clinical examination must be negative for signs of

syphilis. This of necessity includes examination of the skin, mucous membranes, special senses, central nervous system, and the bony structure. If manifestations of the disease are found on such examination, the patient is no longer considered to have latent syphilis.

3. Examination of all the factors in the spinal fluid must be negative.

4. An examination of the cardiovascular system must be negative in that no signs of aortic stiffening or enlargement, aortitis, aortic valvular incompetency, or aneurysm must be noted. This examination should also include teleroentgenographic examination of the thorax.

5. The flocculation, precipitation, or complement-fixation reactions of the blood may be either negative or positive.

6. When the foregoing factors are once estimated, repeated reexaminations at annual intervals are necessary to determine that their status remains unchanged and that clinical signs of syphilis do not become manifest. Accordingly, a diagnosis of latency is not possible at the first examination but can be made only after the clinical and laboratory status has been determined and repeated examinations at subsequent periods of observation have indicated that the latent phase is of a permanent nature. Each annual reexamination that reveals no change in the patient's status adds material significance to the value of the diagnosis, and each year thereafter that the examination shows no change indicates that the latency is becoming more permanent.

Latency has another important factor, namely, that of resistance or the defensive mechanism. It has already been pointed out that latent syphilis is divided into early and late latency. This subdivision is made because it is during the first four years of the disease that the patient's defensive mechanism against the infection shows signs of developing. This fact is well illustrated in a study of the spinal fluids of patients during the first four years of their disease. Briefly this study revealed that in a group of patients who had received no treatment for syphilis and who had had the disease for a year or less, examination of the spinal fluid revealed abnormalities in 33 per cent of the cases; during the second and third years the incidence of positive spinal fluids was respectively lower, and

by the fourth year the incidence of spinal fluid abnormalities had decreased to slightly more than 1 per cent.

It has likewise been shown that if a positive spinal fluid has not developed by the fourth year of the disease, the chances are 99 per cent in the patient's favor that his spinal fluid will henceforth remain negative. No doubt a similar situation prevails in regard to cardiovascular involvement, but at this time there is no way by which the earliest involvement of the aorta can be determined. The factor of resistance is essential to the development and maintenance of latency, but there unfortunately is no rapid method by which one can appraise a patient's resistance to syphilis. A means of measuring the defensive mechanism of the patient against the disease is one of the paramount problems which today confront the syphilologist. The development of nonspecific therapy has been the result of an effort to stimulate these factors of resistance against disease. It may be said, however, that a patient who manifests and maintains latency has organized or is in the process of organizing a satisfactory defense against the infection.

It is unfortunate that all patients for whom a tentative diagnosis of latent syphilis is made do not remain in that state. The time factor and the acumen of the diagnostician are factors which materially influence the frequency with which such progression of the disease is noted. When the diagnosis of latent syphilis is made in a case in which the disease is of fifteen or more years' duration, the state of latency will probably remain permanently. On the other hand, a similar diagnosis made when syphilis is of approximately five years' duration usually means that treatment and more frequent annual examinations are necessary to make certain that latency is maintained. The reason for this is that the great majority of the serious sequelæ of the disease are recognizable by the fifteenth year.

When signs of cardiovascular syphilis develop while a patient is under observation for latent syphilis, the diagnosis of latency is immediately discarded. On the other hand, if a patient with clinical signs of neurosyphilis becomes serologically negative and free from symptoms, the diagnosis remains neurosyphilis but may be qualified by the addition of the term "arrested": in such a case a diagnosis of latency is not possible.

In the essentials laid down for the making of the diagnosis

of latency the comment was made that the serologic tests of the blood may be negative or positive. This is simply another way of saying that latent syphilis may be recognized and so diagnosed irrespective of the blood tests. If a patient is adequately treated for acute syphilis and a negative flocculation or Wassermann test develops and he has a negative spinal fluid and examination of the cardiovascular system is negative, a diagnosis of latent syphilis is warranted. Repeated reexaminations which show an unchanged status for a five-year period may then permit of "parole" or even of the diagnosis of "cure." If a similar patient with early syphilis is likewise adequately treated but retains the positive flocculation or Wassermann test, although all other examinations are negative the diagnosis of latency is also permissible even though there may be need for further treatment; the likelihood of clinical progression, however, must be constantly borne in mind. If the patient with latent syphilis has had the infection for many years and the serologic tests spontaneously change from positive to negative, the diagnosis need not be changed. It is quite common to encounter a patient who has had syphilis for many years and whose serologic tests remain positive. These cases cause both the physician and patient considerable concern because of the inability to obtain a negative blood test.

Thus far I have endeavored to show that the status of the serologic test of the blood is of no significance in latency, although it must be emphasized that the diagnosis of latency is warranted only after examinations of the spinal fluid, cardiovascular and visceral systems and special senses are negative. It is unfortunate that latent syphilis and Wassermann-fastness are frequently confused. Latency may accompany Wassermann-fastness. However, Wassermann-fastness is frequently the result of aortic disease or a positive spinal fluid. Accordingly, when the question is asked as to how to treat a Wassermann-fast patient, the answer must be to determine first, if possible, why the blood test remains positive, such investigation to include the same diagnostic procedure used for the recognition of latency. As Wassermann-fastness may be due to syphilitic visceral disease and may be a part of latency, the patient who has a permanently positive blood test must be scrutinized more frequently for signs of clinical progression of the disease than the serologically negative patient with latent syphilis.

The treatment of latent syphilis is the treatment of the problem presented by the individual patient, because it is not logical to systematize treatment of this phase of the disease in a manner similar to that in which treatment of acute syphilis can be regimented. It is possible, however, to discuss to a certain extent the systematic treatment of latency when the cases are grouped according to the duration of the syphilis, the age of the patient and the amount of previous treatment. It should be recognized, however, that these suggestions in regard to the treatment of latency are flexible and that numerous factors, such as the patient's personality, the degree of syphilophobia present, and the status of his health aside from syphilis, are of great weight in deciding that treatment is or is not necessary. The discussion of treatment lends itself to the citing of various case types which illustrate the variables in the treatment of latent syphilis.

In the case of the young adult whose syphilis is of five years' duration and is in the latent phase and whose serologic test of the blood is positive, the amount of treatment previously received and the patient's sex are of importance in determining the therapeutic program. If the patient is a young man of thirty-two or thereabouts who has had long and intensive treatment with a minimum of fifty injections of arsphenamine and twice as many injections of bismuth or mercury, it will probably be advisable to place him on observation and have him undergo annual reëxaminations. If it seems feasible he may, however, be given two courses of bismuth, fifteen injections each, twice a year for three years, following which observation periods may be instituted. If a patient of similar age whose syphilis is also of five years' duration had received a comparatively small amount of treatment at the time he had acute syphilis, that is, eight to ten injections of arsphenamine and fifteen to twenty injections of bismuth, it would seem advisable to give him a complete course of treatment, consisting of at least thirty injections of an arsphenamine and sixty injections of one of the heavy metals, followed by two or three years of bismuth therapy as outlined in the previous instance.

The sex factor adds a somewhat different aspect, inasmuch as in women of this age the likelihood of pregnancy requires that in the presence of latency and positive serologic tests the

treatment be more strenuous and prolonged. Especially is this true if the patient becomes pregnant, because latency does not assure the mother of a nonsyphilitic offspring. Prolonged and repeated courses of bismuth have been more successful in producing serologic negativity in cases of latent syphilis than have combined arsphenamine and bismuth therapy, and they have proved decidedly superior to treatment by arsphenamine alone.

In the case of middle-aged adults the sex of the patient is of less significance because there is less likelihood of pregnancy. The male adult of forty-five who acquired the infection fifteen years previously and is found to have latent syphilis and a positive blood test presents a problem in which the need for treatment is materially influenced by such factors as his general health, his attitude toward his condition, and the amount of previous treatment. If treatment was wholly inadequate at the time the acute signs of the disease were present, or if the presence of the disease was unknown prior to the time of examination and no previous treatment had been received, it is probably advisable to give several courses of arsphenamine and bismuth or mercury, followed by several courses of bismuth each year for two years. However, if the patient has received a great deal of treatment off and on for many years but the serologic tests have been uninfluenced by it, it is advisable to place him on observation. He should be reexamined annually to make certain that the positive test is not due to syphilitic aortic disease or to some other visceral complication. If a spinal fluid test was found to be negative during latent syphilis, repetition of the test is not necessary. Reassurance that the positive blood test is not attributable to visceral syphilis or to syphilis of the central nervous system is a means of educating these patients to the insignificance of the positive blood test. The experience of those who have used nonspecific therapy in a large group of cases of latent syphilis in which a control study was carried on simultaneously on a similar series of patients who were only observed and were not treated, shows that nonspecific measures in the form of fever therapy of all sorts are of no material value in reversing the serologic test to negative. In a group of patients with latent syphilis, observed for ten years, who did not receive treatment of any type, 85 per cent became serologically negative and showed no signs of clinical progression.

A third group of patients includes those with latent syphilis who are approximately sixty years of age and who have had syphilis for thirty years or longer. The factors of sex, previous treatment, and the patients' concern over the presence of the disease are of less significance than in the cases previously cited. In the majority of these cases the presence of the disease may well be ignored; occasionally, mercury and chalk and small doses of potassium iodide may be given by mouth; only rarely is it necessary to give such patients arsphenamine and bismuth. These patients have controlled their infection satisfactorily for thirty years, they are asymptomatic and free from signs of syphilis, and have long since passed the time when the great bulk of patients with syphilis manifest the serious complications of the disease. Accordingly, such patients are not in need of drastic treatment because of a positive Wassermann test but only of treatment for syphilis as it influences some other intercurrent disease.

In between these three main groups of patients there are many different manifestations of latent syphilis, and in some instances treatment is advisable and in others is unnecessary. In determining the need for treatment of these patients, the potency of the associated findings, the significance of the historical data, and the willingness of the patient to coöperate by reporting for annual reëxaminations are the factors which are to be considered in conjunction with the thoroughness of the examination which warranted the diagnosis of latency.

Latent syphilis, especially during the late phase, is for all practical purposes not considered as an infectious period of syphilis. Treatment is rarely needed to prevent dissemination of the disease to others by patients in this stage.

#### SUMMARY

Latent syphilis is a transient or permanent phase in the course of syphilis. It can be diagnosed as such only after a thorough series of examinations and tests which eliminate the presence of active syphilis. Observation of the patient over a period of years may be necessary to substantiate the diagnosis. The flocculation or complement-fixation test may be either negative or positive in latent syphilis. The need for treatment

of a patient with latent syphilis is dependent on the age of the individual and the duration of his disease. These data may be augmented by the amount of previous treatment, the thoroughness with which the examinations were carried out in the making of the diagnosis, the status of the patient's general health otherwise, the possibility of pregnancy, and the patient's attitude toward his disease.

## FEVER THERAPY FOR GONOCOCCIC INFECTION: III

ARTHUR U. DESJARDINS, WALTER C. POPP AND  
LOUIS G. STUHLER

---

MARCH, 1935, we reported the results obtained with fever therapy in thirty-three cases of gonococcic infection of the urethra, epididymis, prostate gland, uterus, fallopian tubes, and articulations. Of the twenty-nine cases in which the patients had received complete treatment before that date, in twenty-five (86.2 per cent) complete and permanent cure resulted. The average number of sessions of fever required to effect a cure in the majority of cases was found to be 5.4. For a time, before March, 1935, the patients were uniformly subjected to five hours of sustained fever, with the rectal temperature between 106° and 107° F. (41.2° and 41.7° C.), and this was repeated from three to eight or even ten times at intervals of from four to seven days. It was soon discovered that, with such relatively long intervals between sessions, the urethral or vaginal discharge returned. At that time, in fact, the return of urethral or vaginal discharge was empirically regarded as a sign that further treatment was necessary. It was apparent that the intervals between sessions of treatment were too long, and the first improvement in technic was to shorten this interval, because it was realized that to wait for the return of discharge was undoubtedly to lose some, if not most, of the advantage gained. Thenceforth, an interval of two days between sessions was allowed, and the results improved considerably. In spite of this improvement, however, the condition in an appreciable percentage of cases proved resistant to treatment. As previous experience had led to the conviction that the two principal factors in the influence of fever on gonococcic infection were the degree and duration of the temperature, the next step

seemed to be to increase the length of the sessions. However, since various reasons, such as the sensitiveness of the skin of some patients or the importance of allowing the cardiovascular system to adapt itself to the treatment, made it seem unwise to increase the duration of the initial sessions, these were not prolonged beyond five or six hours at temperatures of 106° to 107° F. But if, after the second session, the smears and cultures were still positive, the third session was extended to eight hours. After one or two sessions of eight hours at the same temperature, if the smears and cultures still remained positive, the next session was extended to ten hours. Fortunately, it was found that in only a minority of cases were more than five sessions required. Nevertheless, in a few cases, even after several sessions of from five to ten hours, gonococci could still be found. When the patient was able and willing to continue, sessions of twelve hours at the same temperature were given, and the infection was cured. In a few other cases in which the condition forbade such prolonged treatments, or the patients were unwilling to submit to them, the infection was not cured. The reason for such failure in a small percentage of cases undoubtedly was that the strains of gonococcus responsible for the infection in these cases were exceptionally resistant to heat.

As a result of the foregoing improvements in technic, the percentage of cases in which cure was effected increased to 92, as reported in 1936. Since then the treatment of acute and chronic gonorrheal urethritis, with or without complications, has continued along much the same lines and with only slight additional modifications in technic.

Our present purpose is to report the results obtained from the inception of this work to July 1, 1936. From the very beginning, by the way, the cases selected for treatment have been chosen by the clinician and the urologist, and the question of cure has been decided by the urologist and clinician, after repeated negative smears and cultures. At no time have the physicians who supervised the treatment had any voice in deciding whether any patient was or was not cured.

Another point must be made clear. This is that when repeated smears and cultures have shown that a patient was apparently cured, we have nevertheless insisted in every case on

giving two additional sessions of treatment, in order to prevent any possibility of recurrence. That this policy has been wise is shown by the fact that, whenever a patient returned three or more weeks later and tried to make us believe that he was the victim of a recurrence, we have always succeeded in making the patient admit another exposure.

We are aware that the technic employed has been criticized by some observers on the grounds that a cure requires too many sessions of treatment, and that such an "excessive number of sessions is unnecessary." Those who have made this criticism have not taken into consideration the circumstances under which the work is done, and have not realized that this deliberate policy is dictated by sound reasons. Most of the patients referred to us for treatment come from distances varying between 50 to 1,800 miles, and they come in the expectation of being completely cured. Therefore, it has seemed to us essential to arrange the scheme of treatment so that an absolute cure could be assured to the largest possible number of patients, regardless of other considerations. Moreover, the high percentage of cases in which a complete and permanent cure has been obtained seems fully to justify the technic adopted. When others can show equal or superior results, with a technic that involves fewer sessions of treatment, further technical modifications will be considered, but not until then.

Between December 1, 1933 and July 1, 1936, 210 patients suffering from acute or chronic, simple or complicated, gonorrheal infection were referred for fever therapy. Of this number, forty-one patients did not complete their treatment or the idea of treating them had to be abandoned for various reasons. Sometimes this was because the patient lacked stamina; sometimes it was because of peculiar reactions of the cardiovascular system which made it unwise to proceed further, but in most cases it was because after the initial session, the patient failed to return for subsequent sessions. In any event, these cases must be excluded from consideration. Of the 169 patients who took the treatment faithfully, 152 (90 per cent) were cured and have not had any further physical difficulties caused by the gonococcus. Seventeen patients (10 per cent) were not completely cured, but their condition improved to varying degrees. Among the 169 patients who completed the course were 112

(66.2 per cent) males and fifty-seven (33.8 per cent) females. Ninety-seven (57.4 per cent) were single, and seventy-two (42.6 per cent) were married. The average duration of the infection had been three and three-tenths months. One hundred nine (64.4 per cent) patients had contracted the infection for the first time, whereas sixty (35.6 per cent) had contracted it for the second or third time.

Of the 152 patients who were treated successfully, only thirty-one had simple gonorrheal urethritis. In 121 (79.6 per cent) the infection was associated with various complications. Thirty-six patients had prostatitis; thirty-five had gonococcic arthritis; twenty-six had infection of the pelvic structures; two had infection of Bartholin's glands; seven had epididymitis; four had a urethral sinus; one had fibrositis; of one the seminal vesicles were involved; two patients had proctitis; two had cystitis, in one case the ureter was infected; one patient had pyelitis; two had an abscess of the prostate gland, and one had periurethral inflammation.

In nineteen cases smears and cultures were negative and remained negative after a single session of treatment. In forty-eight cases smears and cultures were negative and remained negative after two sessions of treatment. In thirty-seven cases smears and cultures were negative and remained negative after three sessions of treatment. In twenty-three cases smears and cultures were negative and remained negative after four sessions of treatment. In nine cases smears and cultures were negative and remained negative after five sessions of treatment. In seven cases smears and cultures were negative and remained negative after six sessions of treatment. In one case smears and cultures were negative and remained negative after seven sessions of treatment. In five cases smears and cultures were negative and remained negative after eight sessions of treatment. In two cases smears and cultures were negative and remained negative after nine sessions of treatment. In one case smears and cultures were negative and remained negative after ten sessions of treatment.

Thus it will be seen that in 127 of 152 cases (83.5 per cent), from one to four sessions of treatment were sufficient to rid the patient of the infection. In 136 cases (89.5 per cent), from one to five sessions of treatment were sufficient. In only six-

teen cases (10.5 per cent) were more than five sessions of treatment required to eradicate the gonococcus.

It may be interesting to mention the character and frequency of occurrence of certain disturbances observed during the course of the treatment, and either directly or indirectly caused by it. At some stage of treatment, varying degrees of nausea and vomiting were observed in fifty-seven cases. Sometimes this occurred at the beginning of a session of treatment, when the patient had disregarded the physician's warning not to eat before reporting for treatment. Usually, however, this complication developed at the end of a session or soon after its completion. Having reason to think that this tendency of certain patients might be related to the drinking of 0.6 per cent saline solution while in a fasting state, we attempted to overcome it in two ways: by diminishing the salt content of the solution to 0.3 per cent, and by giving to some patients, from time to time, a small quantity of milk. This last step was intended to quiet the hunger pain so distressing to certain patients, because it was felt that the pain might, in part at least, be the cause of the nausea. That this has been a factor seems established by the fact that a smaller percentage of the patients who were given milk to drink during treatment were disturbed by nausea. However, this has not been tested for a sufficiently long period to warrant absolute conclusions. The percentage of salt in the solution was diminished because it was thought that in some cases the vomiting was probably caused by overfilling the stomach with salt solution. Of course, it was realized that an excessive quantity of water, aside from its salt content, might be responsible for the disturbance, but this seemed a less likely cause than an excess of salt. This technical modification also will have to be tested for a much longer time before the relationship between the percentage of salt and the nausea and vomiting can be ascertained.

Headache is a frequent complaint of patients who receive fever therapy for any disease. It is especially common among patients, the effective treatment of whose condition requires that a high temperature should be maintained for several hours. Eighty-six (56.6 per cent) of the 152 patients included in this report complained of headache. But since, in almost all cases, the headache disappears spontaneously in from one to three

hours after the completion of a session of treatment, special measures to combat this symptom are seldom necessary.

Small, cutaneous vesicles were observed in thirty-eight cases. They promptly responded to ordinary measures and did not have any particular significance. Most certainly they do not justify apprehension, and should not be allowed to interfere with treatment.

Herpes of the lips and sometimes of the nose occurred in thirteen cases. This complication usually developed after the first session of treatment, in patients who admitted being prone to herpes. The lesions should be treated on general principles; they heal rapidly, and seldom need they interfere with the orderly sequence of the sessions of fever.

Tetany, usually affecting the hands and feet, was observed in five cases. In another case the tetanic manifestations did not affect the muscles of either the hands or feet, but did affect those of the abdominal wall. In some cases the intramuscular injection of 10 c.c. of calcium gluconate was sufficient to stop the disturbance. In other cases in which calcium gluconate was less effective, or ineffective, the inhalation of carbon dioxide promptly arrested the tetanic manifestations. As a result of this experience, we have come to rely on carbon dioxide rather than on calcium gluconate. In five other cases peculiar, incoordinate, muscular twitching was encountered. This resembled closely the muscular twitching of certain patients when their temperature rises above a certain level. The cause or causes of such twitching are not clear. In three cases a peculiar palsy of the peroneal nerve was observed; in two cases the palsy continued for one month, and in the third case for about five months. It then disappeared entirely. In all three cases the patients had received ten or more sessions of fever, and some of the sessions had been exceptionally long.

Among the fifty-seven patients who had nausea and vomiting, the material vomited by six contained streaks of blood. Since in not a single case could a gastro-intestinal lesion be found to account for the small quantity of blood, the streaks of blood were thought to be attributable to rupture of capillaries in the gastric or esophageal mucosa resulting from the patient's retching.

One patient had diarrhea; therefore, it does not appear likely that the intestinal disturbance was related to the fever.

#### COMMENT

To say that fever therapy is entirely devoid of danger is contrary to fact. To date, the number of patients treated for various conditions has been 516, and these patients have received approximately 2,580 sessions of treatment. Of this number, one patient died under treatment. The patient was a young woman who had a pelvic infection. She had almost completed her first session of treatment, which had been entirely uneventful, when the pulse rate suddenly fell. She was immediately withdrawn from the chamber; restoratives, including carbon dioxide and oxygen, were administered, epinephrine was injected into the heart three times, but, although the heart began to beat after each injection of epinephrine, respiration failed to return. It is not clear what may have been the factor or factors responsible for her death. This patient's temperature had risen readily, and not the slightest difficulty had been encountered in maintaining her temperature. At no time during the session had her temperature risen as high as 107° F. until just before the pulse collapsed.

This single death among the 516 patients treated gives a mortality of less than 0.2 per cent. Small though this is, the realization that death may occasionally occur from any method of treatment still offers no consolation for the loss of a patient.

## THE DIAGNOSIS AND TREATMENT OF LOW BACK DISABILITY

RALPH K. GHORMLEY

---

THE ever perplexing problem of low back pain may be said to rank among the most important of those problems which confront members of the medical profession today. It produces a tremendous amount of disability and at the same time economic loss of extraordinary importance, as anyone interested in industrial medicine can well testify. That many cases of low back pain are of minor importance is well recognized. The average individual who is troubled by such a pain, if it is transient, usually is able to recover without any serious loss of time or absence from work. However, low back pain, even if minor in nature, becomes of the greatest importance to the patient who is in the least introspective. In another large group of cases severe symptoms are produced; these cases demand serious consideration and the utmost in the way of medical effort and care.

As a working basis, the causes of low back pain can be classified. There is no established classification of back disabilities and many physicians may find suitable to their needs classifications other than that which follows:

1. Posture:
  - (a) Chronic postural strain:
    1. Lumbosacral or sacro-iliac lesions.
2. Trauma:
  - (a) Trauma involving vertebra:
    1. Fracture:
      - (a) Bodies.
      - (b) Pedicles—may produce spondylolisthesis.
      - (c) Laminæ.
      - (d) Facets.
  - (b) Trauma involving joints:
    1. Traumatic spondylosis.

- (c) Trauma involving disks:
  - 1. Narrowing of disk.
  - 2. Avulsion of disk.
  - 3. Rupture of nucleus pulposus.
- 3. Infection:
  - (a) Arthritis, infectious.
  - (b) Spondylitis deformans or spondylose rhizomelique.
  - (c) Fibrositis.
  - (d) Typhoid spine.
  - (e) Tuberculosis and so forth (real localized infections).
- 4. Metabolic and senescent conditions:
  - (a) Hypertrophic changes (may be traumatic).
  - (b) Osteoporosis with pathologic fracture.
- 5. Congenital anomaly:
  - (a) Spina bifida.
  - (b) Sacralization of fifth lumbar vertebra or lumbarization of first sacral vertebra.
  - (c) Anomalous facets (may produce spondylolisthesis).
- 6. Neoplastic conditions:
  - (a) Benign tumors:
    - 1. Osteoma and osteochondroma.
    - 2. Giant cell tumor.
    - 3. Hemangioma.
  - (b) Malignant tumors:
    - 1. Metastatic from prostatic and mammary carcinoma, and so forth.
    - 2. Myeloma.
    - 3. Primary osteogenic sarcoma.
    - 4. Ewing's tumor, and so forth.
- 7. Neurologic conditions:
  - Tumors of the spinal cord and so forth.

The foregoing outline covers most of the possible causes of low back pain. To place a given case of backache in its category may at times be very difficult. More than one of the conditions named may be present in the same case and actual identification of the case with a definite cause may be out of the question. However, in order to approach the subject with the necessary facts in mind a fair understanding of all of the conditions mentioned in the outline is desirable.

The relative incidence of cases attributable to the various causes is of some importance. Chronic and acute strain accounts for a fairly large percentage of the cases and these cases predominate if those of strain caused by trauma are included. The group of cases caused by infection is a large one.

too. Infection and trauma may co-exist in any one case. Actually it is difficult to prove that an "infectious" backache is such. A focus of infection is found in such a case. The focus is removed and after its removal the patient's condition improves. Unfortunately that is about all the proof ever obtained to show that the condition was in any way attributable to a focus of infection. In many cases that is all that is necessary so far as the patient is concerned but from the standpoint of scientific analysis much is lacking. Besides in such a case treatment rarely is limited to removal of foci only and it is difficult to evaluate the relative importance of all of the measures used.

#### PATHOLOGY

The pathology of low back pain is little understood. Marked lesions, such as those of tuberculosis, of malignancy and other destructive lesions are obvious. The great majority of cases of backache, however, are out of the realm of study by a pathologist. Rarely, if ever, does a patient die of a backache. Therefore, the opportunity to describe pathologic changes that may or may not be accountable for the symptoms almost never arises. At times study of tissue removed when operation is performed may reveal changes in the lumbosacral articulations and in the sacro-iliac joints. Smith-Petersen studied the tissue removed from sacro-iliac joints and found "surface fibrosis, myxomatous degeneration of the matrix, replacement fibrosis and calcification." At the Clinic we have studied the changes in articular facets removed at operation and have found the changes typical of traumatic arthritis, that is, fibrillation, and later degeneration of the cartilage with eburnation of the underlying bone. The work of Schmorl has done most to stimulate interest in the pathologic changes in the intervertebral disks. These changes may be the most important of all in cases of chronic lumbosacral strain. Geist was one of the first to emphasize these changes. Williams pointed out the importance of changes in the disks in cases of lumbosacral pain with sciatica. Mixter and Barr reëmphasized the fact that avulsion of the disk into the spinal canal may occur and thus give rise to symptoms. They expressed the

belief that this is a much more common condition than heretofore has been recognized. Freiberg and Vinke gave the most plausible explanation of the association of sciatic pain with changes in the sacro-iliac joint.

With this brief sketch of the up-to-date concepts of the pathologic changes which underlie the more common types of low back pain, it may be admitted that there is still a great deal to be learned on the subject.

## HISTORY

Taking of the history in this condition, as in any other disease, must be accurate and careful. Indeed it may be the most important of all the procedures. Before or during the taking of the history the patient's background with reference to the pain should be learned. This is most important in industrial insurance or medicolegal cases and may be very difficult to obtain from the patient himself. In other cases, not in any way complicated by the problem of industrial compensation, the patient may have set up certain conceptions of his own such as "that the pain is due to kidney trouble" or "a vertebra is out of place" and many other misconceptions to expression of which the inquirer must listen patiently and then get his own history by direct questioning.

In taking the history certain facts must be brought out, among the most important of which are: (1) mode of origin, whether insidious or following injury; (2) type of pain, whether static or constant and whether appearing at night or in the morning; (3) means of relief of pain, whether relief can be obtained by rest, application of heat, and so forth.

If from the preliminary inquiry a true insight into the patient's status relative to industrial compensation or medicolegal involvement is not obtained, effort should be made by other means to get this necessary information. The physician must obtain it before he can deal intelligently with the case.

It is often helpful, before formulating treatment, to inquire of the patient what other treatment has been tried, if any, and with what success. In many instances if adequate conservative measures, under the direction of competent physicians, have failed, much time can be saved by not repeating those measures.

## EXAMINATION

Examination of a patient troubled with low back pain always should be carried out with the patient's back and hips well exposed. If a cape is worn, it should be reversed, exposing the entire back.

With the patient standing, the following should be sought: the presence of list or sciatic scoliosis (Fig. 42); flattening or

Fig. 42.—Typical attitude in sciatic scoliosis. The list may be toward or away from the painful side.

increase of lumbar lordosis; atrophy of buttocks; prominence of the hip and so forth.

The patient should be asked to bend forward and then the physician should note particularly whether spinal motion is limited and to what degree. The normal spine should arch in the lumbar region on bending forward. The patient should keep his feet on the floor and his knees should not be flexed as he bends forward. When he bends to the side his elbows

should be in the plane of the body. In this way the spine is straightened and the exact amount of bending to the side can be accurately noted.

Regions of tenderness should then be noted. The presence of tenderness is usually best determined by observing the patient's response to pressure. Deep pressure is often necessary, particularly if patients are obese or heavily muscled. Real pain will be elicited in many cases and will be manifested by wincing, squirming or a protest on the part of the patient. Percussion with the fist over the spinous processes using a knuckle to strike the bony prominences, may help to elicit deep-seated tenderness. Percussion should be used over the posterior superior portion of the spinal column. Any prominences, such as the trochanters and iliac crests, should be palpated to determine the presence or absence of tenderness.

Smith-Petersen has outlined a routine examination in such cases which may be of help to those interested in this subject. The same author has described in more detail his method of examination in Christopher's "Textbook of Surgery."

After examination in the standing position, the patient should be allowed to sit on an examining table with knees and hips flexed. Motions should again be observed and tender regions noted.

With the patient supine, his ability to tolerate raising of the straight leg should be tested and Gaenslen's test should be carried out. The legs should be measured. Ober's test for contracture of the iliotibial band also should be done. This test is carried out as follows: "The patient lies on his side with the thigh next to the table and flexed enough to obliterate any lumbar lordosis. The upper leg is flexed at a right angle at the knee. The examiner grasps the ankle lightly with one hand and steadies the patient's hip with the other. The upper leg is abducted widely and extended so that the thigh is in line with the body. If there is any abduction contracture the leg will remain more or less passively abducted depending upon the shortening of the iliotibial band. This band can be easily felt with the examining fingers between the crest of the ilium and the anterior aspect of the trochanter."

The patient should then be asked to lie prone on the examining table, when again regions of tenderness should be

noted and hyperextension of the hips, as well as rotation of the hips, should be noted.

With these facts in hand the physician can come to some conclusion regarding the type of lesion he is dealing with. Of the various points in the examination, consistently localized tenderness probably is of the greatest importance in determining the type of lesion. Tenderness, of course, is a subjective manifestation and therefore its importance may be questioned. In most instances an experienced examiner can tell whether a patient's response to percussion or palpation is overdone or feigned. The moment of response is never accurately timed by the malingerer. He responds too quickly as a rule; sometimes too slowly. His attitude in other ways is often characteristic of the "compensation neurotic" and gives him away.

Limitation of motion, if marked, generally indicates an inflammatory process, that is, some type of arthritis, spondylitis or myositis. Usually, motion of patients who have sacro-iliac strain is not limited when they are in the sitting position, whereas in cases of lumbosacral strain motion is limited both when the patients are standing and when they are sitting.

When examination of the back has been completed the question remains as to how much of a general examination is necessary. In the average case of acute back strain no further examination usually is necessary. In cases in which the condition has become chronic, or in any case in which infection may be suspected as the basis of the difficulty, complete examination should be carried out. This should include routine examination of heart, lungs and abdomen; search for foci, particularly about the teeth, the tonsils, the prostate gland of the male and the general pelvis of the female. If there is any sciatic pain, neurologic examination should be made. Such an examination should be done by one who is familiar with neurologic conditions if a competent neurologist is not available.

Laboratory examinations of importance are urinalysis, flocculation tests, estimation of hemoglobin and enumeration of leukocytes. Roentgenologic examination will be discussed more fully later. If neurologic examination gives sufficient evidence to warrant lumbar puncture this should be done and the spinal fluid should be examined. The total protein is the most important factor in examination of spinal fluid.

The roentgenologic examination should include, as a very minimum, anteroposterior and lateral (Fig. 43) views of the

Fig. 43.—Lateral view of lumbosacral joint.

lumbosacral regions, including the lower lumbar vertebræ, the sacrum and the sacro-iliac joints. If these last are the center

Fig. 44.—*a* and *b*, Three-quarter views in the same case as that represented in Fig. 43. In *b*, the damaged facet is clearly seen and is indicated by arrows

of attention, stereoscopic anteroposterior views should be made. or changes in these joints, unless they are extensive, cannot

be accurately read from flat plates. In addition to the foregoing views, oblique views to demonstrate the lower lumbar facets should be made (Figs. 44 and 45). Finally, if the lumbar puncture and the neurologic examination arouse suspicion of a damaged intervertebral disk or of tumor, lipiodol should be injected and roentgenologic examination made. Thus, a formi-

Fig. 45.—Two three-quarter views and a lateral view in a case of lumbo-sacral spine. Bilateral damage to facets is evident between fourth and fifth lumbar vertebrae.

dable array of roentgenologic examinations may be necessary before completion of the studies in one of these cases.

The important features to note in examination of roentgenograms are:

1. Sacro-iliac regions:

(a) Presence of marginal osteitis.

(b) Destructive changes:

1. Inflammatory.

2. Malignant.

(c) Irregular destruction such as is seen in early spondylitis deformans.

(d) Fusion.

(e) Hypertrophic marginal changes (often of little or no significance).

2. Lumbo-sacral joint:

(a) Changes in bone:

1. Marginal hypertrophic changes.

2. Shape and size of vertebral body.

3. Character of bone, particularly evidence of osteoporosis.

4. Congenital anomalies, particularly spina bifida and sacralization of the transverse processes. If sacralization is present, whether it is complete or whether there is an obvious joint between the process and the sacrum should be noted.

5. Destructive lesions: malignant, inflammatory.

6. Sclerosing lesions: malignant, inflammatory.
  7. Presence of spondylolisthesis.
- (b) Changes in disks:
1. Narrowing or thinning of disk.
  2. Ballooning of disk associated with osteoporosis of vertebræ.
  3. Increased density of margins of the vertebræ.
  4. Prolapsed nucleus pulposus (Schmorl bodies).

### DIFFERENTIAL DIAGNOSIS

In dealing with low back pain of all sorts, neurologic conditions must be thought of first in differential diagnosis. The outline of examination which has been given has revealed the importance of the opinion of a neurologist; in many instances this may be said to be an essential part of the routine examination.

Inflammatory lesions, such as those of tuberculosis, must be excluded. As a rule evidence of tuberculosis of the lower lumbar vertebræ or sacro-iliac joints can be fairly readily recognized in the roentgenogram. Often, too, an abscess is present either in the iliac fossa, the gluteal region, or below Poupart's ligament. Such an abscess often produces spasm of the psoas muscle on the side affected and a "soft-parts shadow" may be visible in the roentgenogram.

Other inflammatory lesions occasionally may be seen, particularly those which accompany acute or subacute infections of pyogenic origin. In the presence of such lesions there are, as a rule, signs of infection, fever, localized softening, inflammatory masses, abscesses and so forth. Occasionally a sacro-iliac joint may become fused by an acute infectious process without any suppuration.

Tumors, both benign and malignant, must be ruled out. The subject of neoplasms of bone is such an extensive one that elaborate consideration must be omitted here. However, it is well to remember that such tumors do occur and may constitute a troublesome diagnostic problem. As a rule any low back pain that does not subside under a reasonable amount of treatment of the types usually given must be suspected of having its origin in a malignant neoplasm. Sometimes such a lesion will not be found at the time of examination and it will be necessary to ask the patient to return at a later time for reëxamination.

In examination of females the various possible pelvic lesions must be ruled out by examination of the pelvis. As a rule, the skeletal types of backache are not so much exaggerated during menstrual periods as are those caused by pelvic lesions. It must be remembered, however, that some increase in pain may accompany menstruation in many cases of sacro-iliac backache.

Various lesions of the male genito-urinary system may cause confusion at times. Lesions of the kidneys and ureters usually cause pain that is localized higher and is referred to the scrotum. Lesions of the prostate gland and urethra, as a rule, cause perineal pain; this is rarely a symptom of lumbosacral or sacro-iliac lesions.

Patients who have osteoporosis usually are more than fifty years of age. It may be a manifestation of parathyroid disturbance, although, as a rule, this cannot be demonstrated. The condition usually is designated "senile osteoporosis." The findings are the roentgenologic changes of osteoporosis, often together with pathologic compression fracture. The disks, too, have undergone the rather characteristic ballooning seen only in this type of lesion. Pain is severe and usually is static in type.

Much has been written from time to time regarding the importance of congenital lesions of the lower vertebræ and sacrum. Spina bifida is usually of little or no significance with reference to the pain. In the presence of more extensive lesions, the pedicles and facets may be so involved as to produce disturbances in the stabilizing structures of the vertebræ, thus leading to traumatic or static changes in the lumbosacral joints which become painful. Such changes may be the underlying cause of spondylolisthesis, in which case too they are significant. In the extreme cases of spina bifida, with meningocele and myelodysplasia, the lesion is of course of primary importance.

Sacralization of the last lumbar vertebra or lumbarization by the first sacral vertebra often may be without any significance. If the sacralized transverse process is firmly united to the sacrum no movement can take place between the anomalous vertebra and sacrum. The intervertebral space is narrowed or obliterated and the facets are rudimentary or obliterated.

If only partial sacralization exists, so that movement may be present between the anomalous vertebra and sacrum, inflammatory processes may be set up which may produce symptoms.

### TREATMENT

The problem of treatment of low back disability is still of major importance. Various physicians have argued that this or that type of treatment is the appropriate one. The truth is of course that no one method is appropriate in all cases. Many types of treatment may help, many may even appear specific in some instances, but any one experienced in handling such cases knows that often he is disappointed.

In the acute case of back strain, in which there is a history of definite injury by twisting or falling or lifting, the most important part of the treatment is rest. In such cases, as a rule, much more headway will be made and recovery will be much more rapid if rest is given than if it is not. As a rule, it is difficult to persuade the patient to accept rest. Combined with rest several measures may be used, such as (1) firm strapping with adhesive tape across the pelvic and lumbar region, which acts as the simplest sort of splint; (2) placing of a scultetus binder about the pelvis and lower part of the abdomen may be of help if the patient is recumbent; (3) use of a fairly firm bed, preferably a "fracture bed," with boards on the springs and a firm hair mattress. There is little doubt in my mind that if more acute back strains were treated with complete rest in bed at first, there would be many less chronic back strains to treat.

Besides rest and fixation by strapping with adhesive tape or by a scultetus binder, heat and massage should help. Of course, when adhesive straps are applied, heat and massage cannot be used. If choice must be made between rest and adhesive strapping on the one hand and rest, heat and massage on the other hand, the latter usually will prove the more effective.

For recurrent, acute back strain, or "lumbago," more elaborate examination is essential. If obvious reasons for the pain can be found, such as skeletal changes, more radical treatment may be necessary. Usually in these cases, if ambulatory treatment is to be tried, a well fitted cloth corset or belt should

be made. Women will seldom wear a heavy canvas belt but usually will consent to wearing a cloth corset. Such a corset should, above all else, be carefully fitted. Many elaborate types of "surgical corset" are advertised. Their very complexity makes it difficult for the average patient to adjust them properly or to wear them comfortably. My own choice is a corset with laced back which should be applied and the laces drawn comfortably taut each time it is put on. In this way a comfortable, snugly fitting support is obtained. For men, a canvas belt, with or without a sacral pad, usually is the most satisfactory type of splint. Together with use of the corset, baking and massage should be carried out. Often a patient can procure some sort of radiant heat lamp and take such treatments at home, himself, if time or money does not permit his taking the treatments under the supervision of his physician or of such physiotherapists as his physician may recommend. Usually it will be necessary to continue such treatment for many months. After the pain has subsided, exercises should be commenced to rehabilitate the muscles which are bound to become more or less atrophied during the period of fixation. Such exercises should be simple, postural exercises designed to develop particularly the erector spinæ muscles and the gluteal muscles. An excellent substitute for such exercises is swimming. Probably no form of athletic diversion is more suitable than swimming and the patient who can swim, and who has the opportunity to do so, should continue with it until normal muscular strength has been restored; this will require several weeks.

For acutely recurrent attacks of what is commonly called sciatic scoliosis, manipulative treatment may be useful. In our experience at the Clinic, however, manipulative treatment rarely offers more than temporary relief when the backache is of the severely recurrent type. Mennell has described the various types of manipulation more commonly used.

In more severe cases, or in those which have become chronic, and in which pain is either continuous or severe, recurrent or disabling, much can be gained by treatment in hospital. Such treatment can serve a twofold purpose: first it offers the best conditions for the attempt to relieve the patient; second, it gives the physician a chance to observe the patient's

response to various sorts of treatments and thus allows him to get a better insight into the diagnosis and prognosis. Our routine treatment at the Clinic is as follows: (1) rest in bed with a fracture board on the springs and a firm hair mattress; (2) traction of 6 to 8 pounds (2.7 to 3.6 kg.) on each leg, employing moleskin adhesive tape or padded ankle cuffs; (3) some sort of support under the lumbar part of the spinal column either a pillow or a sling padded and counterweighted to a point which the patient can stand; (4) daily physical therapy, usually baking and massage alternating with diathermy until it is determined which type of treatment gives the patient the most relief; (5) epidural injections if there is sciatic pain and if relief of pain is not obtained by traction.

Usually on such a program the patient will complain of more pain for the first two or three days. About the fourth day some subsidence in the pain should be looked for if the patient is going to respond to such treatment. If pain is relieved and muscular spasm is decreased, the treatment should be continued ten days to two weeks, and then a gradual resumption of activity, wearing of a well fitted corset, continued rest and application of heat and massage at home should be prescribed.

Craig and I have reported elsewhere the details and results of such treatment. In a considerable number of such cases relief can be afforded by this combination of treatment.

If relief comes with the treatment but there is immediate recurrence of the pain on resumption of walking, more radical treatment must be considered. If skeletal changes, such as narrowed disks and changes in the facets exist and if conservative treatment has been given adequate trial without benefit, and if neurologic lesions have been excluded, surgical operation of some type may be indicated, probably fusion of the lumbosacral joint or of the lumbosacral and both sacro-iliac joints, depending on the findings on physical examination.

The original descriptions of the various types of fusion operation can be found in medical journals of the last ten years. The lumbosacral or sacro-iliac joints can be adequately secured by one of these methods.

It is our custom to keep the patients in bed, on a frame, for six weeks after operation, then to allow a minimum of activity until the end of four months when, if roentgenograms give evi-

dence of sufficient fusion, more nearly full resumption of activities can be permitted. At this stage, exercises to rebuild the weakened muscles should be instituted, again simple posture exercises, or swimming can be utilized.

Ober's fasciotomy has had a promising start in the surgical treatment of low back pain; whether the patients so treated will be permanently cured or not, remains to be seen. Details of the method will be found in the author's original article.

More recently, Mixter and Barr have emphasized the importance of avulsion of the intervertebral disks for back pain. This seems reasonable and logical. Time will show what is the proper method of handling these cases. In those cases in which neurologic signs and symptoms are found, excision of the offending disk, or at least of a portion of it, must be carried out. If, however, there are no real pressure symptoms it is questionable whether laminectomy is necessary in all such cases. Many patients may respond to lumbosacral fusion and some may require fusion as well as removal of the disk.

## TREATMENT OF FUNCTIONAL MENSTRUAL IRREGULARITIES

DELLA G. DRIPS

---

OF the many clinical problems in gynecology, the treatment of functional menstrual irregularities has always held much interest and has become more fascinating with advancement in knowledge of the function of the glands of internal secretion. Physicians who are called upon to treat young women complaining of such irregularities must have some understanding of the physiologic and biologic problems involved and keep in touch with what is constantly being revealed by experimentation. To be able to use the newer hormone preparations intelligently one must have followed the experimental work leading to the isolation of the hormones and be familiar with their biologic reactions.

By a functional menstrual irregularity is meant some disturbance of the rhythm of the cycle or some variation in the normal duration or amount of menstruation due solely to a disturbance of the physiologic function of one or more of the glands involved in normal, regular menstruation. Of chief concern are the ovaries and the anterior lobe of the pituitary gland. Usually a functional menstrual irregularity dates from the onset of menstruation, or at least becomes evident during the developmental period. If a young woman can be carried along until the end of this period, that is, to the age of from twenty-one to twenty-three years, the normal physiologic function of the glands involved often finally asserts itself. Occasionally, functional disturbances first become evident after parturition.

Sterility or one-child marriages are very common in cases in which menstrual irregularities are not corrected, as would be expected. Before the newer methods of treatment came into

vogue, of a group of 144 married women who complained of an amenorrheic type of irregularity, with an average length of married life of 6.1 years, 53 per cent were sterile, and for the others the average number of pregnancies was 1.4. Of seventy-seven women who complained of functional metrorrhagia and who had been married on an average of 5.9 years, 44 per cent were sterile, and the average number of pregnancies among the others was 1.6.

Functional menstrual irregularities may be divided into two types: (1) the amenorrheic type, the patient complaining either of skipping periods, a tendency to longer intervals between periods, or of less flow or a shorter period, or of all of these symptoms; and (2) the metrorrhagic type, the patient complaining of a shortening of the interval between periods or of more prolonged or profuse periods often with continuous bleeding. Both types are assumed to be due to a hyposecretion or complete absence of one or both ovarian hormones: the amenorrheic type to a hyposecretion or absence of both the estrogenic and the luteal hormones of the ovaries, and the metrorrhagic type usually to a hyposecretion or absence of the luteal hormone. It is not unusual, however, to have continuous bleeding associated also with an absence of estrogenic hormone in the urine and an atrophic type of uterine endometrium.

In the amenorrheic type of irregularity the uterus tends to become smaller, and the endometrial change over that of the resting stage depends on the amount of hormones present. There may be very little proliferation and little differentiation premenstrually. The uterus of the metrorrhagic woman usually is entirely normal in size, or even larger as a result of the sufficient estrogenic hormone present. Proliferation of the endometrium occurs and often is much exaggerated over normal, but the secretory or differential phase is not reached. Bleeding may occur from dilated sinuses through ruptured capillary walls, but this is not true menstrual bleeding. Luteal hormone which brings the endometrium into the true secretion phase is lacking.

Either of the two glands chiefly concerned with menstruation, the ovaries or the pituitary (anterior lobe) may fail and an irregularity ensue. The type of irregularity in each case may be very similar although with primary pituitary failure,

the rhythm of the cycle is likely to be more disturbed. The patient, however, as a whole presents a different clinical picture in each case. Those belonging to the hypopituitary group are usually overweight and their basal metabolic rates are below normal; they usually complain only of a tendency to obesity and sterility. The women with ovarian hypofunction are usually normal or underweight, their basal metabolic rates tend to be normal and, in addition to sterility, they usually have numerous complaints associated with the menses: soreness of the breast before the periods, a migraine type of headache before or at some time during the period, menstrual pain of either the uterine or ovarian type before or with the period, low backache, aching in the thighs, gastro-intestinal complaints such as gas and bloating, increased nervous irritability before periods, and even vasomotor disturbances, especially hot flashes between or with the menses. All of these symptoms of ovarian failure are noticeable in most women with the onset of the menopause period. It is believed that they are not directly due to a lack of the ovarian hormones, but to an excess of anterior pituitary gonadotropic hormone, as they are not present in primary pituitary hypofunction with secondary ovarian failure. These are not only clinical assumptions, but are borne out by determinations of the content of estrin and prolan in the blood and urine in these cases. In primary ovarian failure the content of estrin is found to be lower than normal, and prolan is normal or in excess, depending on the degree of ovarian failure. In primary pituitary failure, both estrin and prolan are lower than normal.

One small group into which some cases of amenorrhea fall might be mentioned here. In such cases it would seem as if some unknown factor were responsible for the amenorrhea. The patients are normal in every way, blood and urinary hormones are present within normal limits, and the uterus is of normal size. These women may become pregnant without menstruating.

It would also not seem amiss here to say more about the methods of determining estrin and prolan in the urine, as one is often dependent on these determinations in deciding which gland's failure is responsible for the patient's complaint. By urinary estrin I have reference to an ovarian hormone found

cyclically in the urine of every woman who is having menstrual periods. It is the hormone of the ovaries that has to do with maintenance of the size and turgor of the accessory organs: the uterus, vagina, external genitalia and breasts. It induces cyclic proliferation of the endometrium of the uterus, and in sufficient quantities in the blood stream suppresses pituitary function. In the mouse and rat this hormone induces the changes in the uterus and vagina that are incident to the state of heat, or estrus; hence its name. At the time of heat there is desquamation of pure cornified epithelial cells from the vaginal wall into the lumen, and the obtaining of such cornified elements alone in a vaginal smear from a castrated adult animal is the positive test for the presence of estrin in any test material injected into the animal. For a determination of urinary estrin it is therefore necessary to extract the hormone from the urine and to inject it into castrated, adult female mice or rats, and, by taking vaginal smears, to test for the estrus reaction, which is the pure cornified smear.

An attempt is made at the Clinic to make determinations as quantitative as possible. The urine is collected for twenty-four hours, 700 c.c. of pooled urine being used. The hormone is extracted and carried over finally into 10 c.c. of olive oil. This is injected in varying doses into from three to six test animals, three injections being given at twelve-hour intervals and vaginal smears being taken twice daily for four days. The smallest total amount of olive oil containing the hormone which when injected into a single rat produces the estrus reaction, as evidenced by the cornified vaginal smear, is then noted. From this is calculated the total rat units of estrin in the twenty-four hour specimen of urine. The amount of estrin excreted in twenty-four hours varies for each day in the normal cycle of every woman; it also varies in different individuals, so that one has to study the estrin excretion of many normal women for several cycles in order to establish graphs of normal estrin content. The greatest excretion of estrin in the urine in any single twenty-four hours occurs midway between menstrual periods. The values for excretion are lowest near the menses. The normal values for the midcycle vary in our series, with the Kurzrock method described here, between 14 and 30 rat units. At present we at the Clinic are using the Smith method,

which extracts both the free and combined estrin, and the values run about twice as high (Figs. 46 and 47).

Prolan in the urine of nonpregnant women is the true anterior pituitary gonadotropic hormone. It can produce in the ovaries of immature rats follicle ripening or luteinization, depending on the amount of hormone; in the great proportion

Fig. 46.—Estrin in the urine of a young woman with apparently normal menstrual cycles. A twenty-four hour specimen of urine was obtained once a week.

Fig. 47.—Estrin in the urine of a young woman with apparently normal cycles. A twenty-four hour specimen of urine was obtained every third day.

of cases, however, with present methods of extraction only follicle stimulation is obtained. At the Clinic we have not attempted to make our prolane determinations quantitative. We attempt by two different precipitation methods to determine only if prolane is present in excessive amount or if it is present in small or nearly normal amounts. In certain cases of dys-

function, when partial or complete ovarian failure is present, prolactin will be present in the urine in excessive or greater than normal amounts. This is what occurs, of course, in the menopause, so if we suspect ovarian failure and excess pituitary function, we use the Aschheim-Zondek alcohol precipitation method: The patient is requested to bring in the early morning specimen of urine, 60 c.c. being necessary for the test. Three or four times this volume of alcohol is then added and prolactin is precipitated, all of the precipitated prolactin finally being obtained in a concentrate of 12 c.c. This amount is then divided and injected into three to six immature female rats, about twenty-one days old and weighing from 27 to 30 gm.—litter mates if possible. Six injections are given at intervals of twelve hours; at the end of 100 hours the rats are killed, the uterus and ovaries are observed grossly and weighed, and the ovaries are put into a fixative, and are later embedded in paraffin, cut and stained. Cross sections of the ovaries of animals that have received injections are then compared with those of a control animal, that is, if possible, a litter mate. We look for evidences of follicle stimulation (increased maturity of any follicles, and an increase in the number of medium size and large follicles, with the formation of antra) and normal corpora lutea; and then compare the weights of ovaries and uterus of the animals that have received the injection with those of the control. These are the criteria for the presence of prolactin in the test extract. The smallest amount of this extract sufficient to produce stimulation represents at least 66 rat units of prolactin to the liter, or 1,000 c.c., which means that prolactin is present in amounts greater than normal, which at most would probably be not more than 16 rat units. When we wish to test for normal amounts, or to see if any prolactin at all is present, as in cases of suspected pituitary hypofunction, we collect 1,000 c.c. of urine. The prolactin is then extracted from this by a method which precipitates much more prolactin than is possible with alcohol. (Levin's tannic-acid precipitation method has been most satisfactory.) The biologic assay is the same.

As a rule, with either of these methods one sees only follicle ripening. The luteinizing hormone, or at least the pituitary gonadotropic hormone, is present in amounts too small to in-

duce formation of corpora lutea. To my knowledge, at no time during the cycle of a normal woman has prolan been found in amounts greater than 25 rat units to a liter, and usually it is not present in determinable amounts except at two periods in the cycle: at some time during menstruation, and again near the middle of the cycle. It is therefore evident that, if possible, it is best to collect the urine for determination of both

Fig. 49.—Cross section of ovary of a rat twenty-one days old after injection of a urinary precipitate obtained with tannic acid. Levin method for demonstrating prolan present in normal amounts or above. Some follicle stimulation is evident. The urine was obtained from a girl, twenty-one years of age, who complained of irregular periods and severe dysmenorrhea. The failure here is assumed to be ovarian as the pituitary response is normal.

estrin and prolan midway between periods, or about two weeks after the onset of the period, and always the first day of the last menstrual period before the collection of the urine should be noted for convenience in judging values (Figs. 48-51).

Most workers have asserted that it is of no diagnostic aid to have solitary or weekly values of urinary estrin and prolan, but that determinations should be made daily, or a determination should be made on each three-day amount of urine over

several weeks. This is probably true when one is trying to determine in a case of primary amenorrhea or amenorrhea of many months' duration whether any ovarian or pituitary function is present, but even here single positive values are very helpful. Whenever possible several determinations are made in order to get a positive value and to obtain some evidence that a cycle is still present. The chief reason, of course, for

Fig. 50.—Cross section of ovary of a rat twenty-one days old after injection of a urinary precipitate obtained with alcohol. Aschheim-Zondek method for excess prolactin. The urine was obtained from a woman, thirty-three years of age, who had not menstruated for nine months. She was having some hot flashes. Marked follicle stimulation here is evidence of excess pituitary function and ovarian failure. There was no estrin demonstrable in a twenty-four hour specimen of urine.

any investigation in these cases of dysfunction is to determine, if possible, where the failure lies—whether there exists a pituitary or ovarian deficiency. Endometrial biopsy is also of aid in these cases, but occasionally the uterus becomes atrophic and stays so even after the cycle gets to going again; the endometrium is reported as atrophic, and one would need to interpret this to mean that no cycle was present when, very often,

estrin is found to be present in the urine, making the prognosis much better.

I have recently studied a group of cases, sixty-two in all out of a total of 109, in which determinations of urinary estrin and prolan were made because of some functional menstrual

Fig. 51.—Cross section of ovary of a rat twenty-one days old after injection of a urinary precipitate obtained with tannic acid. Levin method for demonstrating amounts of prolan normal or above. The urine was obtained from a girl, twenty years of age, who had never menstruated. The marked luteinization is evidence of a high content of urinary prolan, which indicates excess pituitary gonadotropic function. A twenty-four hour specimen of urine was negative for estrin. Only a tiny uterus was palpable, and absence of the ovaries was suspected.

disturbance. These sixty-two women had complained of scanty flow, although their periods had been regular; all but thirteen of them were married and complained of sterility. Thirty-nine of the sixty-two women had various symptoms associated with the scanty flow, chief of which were headache and dysmenor-

rhea. They complained in addition of soreness of the breasts a week before the periods and of a bearing-down discomfort in the pelvis as though the period were coming on, of aching in the lower part of the back, nervousness and irritability, sleeplessness, and a feeling of tenseness, and so forth. Four women were intensely nervous, and had hot flashes before their scanty periods and much nausea and pain with the flow. These women with the severest symptoms we expected might have excess prolactin in the urine and very low values for estrin as we thought that, clinically, these cases represented the most outstanding examples of ovarian failure. Prolactin was found in excess in the urine, but the values for estrin were normal or higher than normal. It appears as if the pituitary, once getting stimulated by a lack of estrin, keeps up its overfunction until the level of estrin gets sufficiently high to suppress it; or we may in some cases be dealing with a true hyperpituitary gonadotropic function. We are at present continuing our investigations in this group of cases. This study served to show the value of hormone determinations. There is no doubt that many of the menstrual abnormalities are due to pituitary hyperfunction rather than to a real lack of estrin. Such symptoms are sore breasts, headache and vasomotor instability with hot flashes. All the women in this group without associated symptoms had amounts of prolactin in their urine too small to be detected by our technic.

Every young woman who complains of a menstrual irregularity is entitled to a thorough general examination (the history of the irregularity being taken carefully), particular attention being paid to her general build, the development of her breasts and external genitalia and to the pelvic examination, with special reference to any local pathologic changes and to the size of her uterus and ovaries. Cystic ovaries are very common in these women with functional disturbances. A roentgenogram of the sella turcica should be made, the basal metabolic rate, and amounts of estrin and prolactin in the urine should be determined, and endometrial biopsy should be performed, when feasible.

When women complain only of sterility, and in borderline cases in which the menstrual periods are fairly regular and normal, endometrial biopsy just before menstruation is invaluable. This alone will tell whether one is dealing with any

deficiency of the ovarian secretions; and, if the uterine endometrium is of the normal premenstrual differentiative type when it should be, the cause of the sterility is probably not endocrine. In cases in which bleeding occurs, it is often necessary to do a curettage for diagnosis. This offers endometrium for study when no organic cause is found for the metrorrhagia. Pelvic exploration has at times to be resorted to in order to rule out ovarian neoplasms or endometrial tumors.

The purpose of treatment in all these cases is, of course, to try and establish at least as normal and as regular menses as the patient considers normal for herself. Essentially, irregularity of menstruation is any deviation from what the patient herself considers normal.

The treatment of the amenorrheic type of menstrual irregularity depends on whether failure is primarily pituitary or ovarian. In the hypopituitary group, the first consideration is the usual overweight. A reduction diet high in vitamins and with sufficient protein is given. As the basal metabolic rate is usually less than  $-10$ , the next consideration is elevation of the rate to around  $-5$ , with an attempt to hold it there indefinitely. If after from three to six months thyroid medication alone does not establish menstruation or correct the irregularity, low-dosage irradiation of the pituitary gland and ovaries is considered.<sup>1</sup> Irradiation is especially considered when one is dealing with amenorrhea of more than six months' duration. In this type of case, low-dosage roentgen therapy offers a good chance (80 per cent) of bringing on a menstrual period, which usually comes on directly after the treatment or five weeks following. When the first treatment is not effective, it is repeated if possible in three months. Whenever it is possible to employ thyroid medication, its continuous use certainly appears to help keep the cycles going.

In cases in which the amenorrhea has not been present more than four or five months, it is possible at times to bring

<sup>1</sup> For the treatment of ovarian dysfunction, we at the Clinic are now irradiating one field over each temporal region, centering over the pituitary, and one field over the front of the abdomen, centering over each ovary. The following technic is used: 200 kilovolts, 10 milliamperes, 0.75 mm. copper and 1 mm. aluminum filters, 50 cm. distance, for five minutes. This represents approximately one-sixth of a skin erythema dose.

rhea. This represents approximately one-sixth of a skin erythema dose.

on a period by intramuscular injections of a preparation of the female sex hormone (progynon-B, 5,000 to 10,000 International units), an injection being given every fourth day. Usually after three or four injections a period ensues; it may, however, ensue after one injection, which is the reason for waiting four days between injections. The next month, injections are repeated on the same days and another period will ensue. After three or four months' treatment the cycle carries on of itself. Single large doses of estrogenic hormone apparently stimulate the pituitary gland. Thyroid medication has been very valuable in straightening out minor irregularities in these cases and especially in those in which sterility is a chief concern. Minor menstrual irregularities in this group treated before the uterus has become too atrophic respond rather easily. The uterus undergoes much more rapid atrophy in cases of amenorrhea of primary pituitary hypofunction than in those in which it is primarily of ovarian origin. For this reason treatment should be begun three months after the onset of the amenorrhea. The earlier treatment is begun the simpler it will need to be, because after marked atrophy of the uterus occurs any form of treatment may be of no avail.

In cases of primary ovarian failure one is confronted not only with the problem of the menstrual irregularity and the associated sterility but, in addition, with the train of symptoms associated with such failure. In considering therapy, then, one strives not only to reestablish regular, normal cycles, but also to relieve the patient's symptoms. The basal metabolic rate in these cases is usually within normal limits, so it is seldom possible to employ thyroid medication; if only small doses are possible, thyroid medication seems to be of value. In cases of amenorrhea of more than five months' duration, low-dosage roentgen irradiation of the ovaries is of value, and it is in this group that periods are frequently reestablished after long intervals because the uterus does not become so atrophic. Values for estrin are not as low as in pituitary amenorrhea, in which pituitary stimulation is lacking. In one of our cases, that of a woman of twenty-six years, the menses were reestablished after seven years of amenorrhea, the first period occurring five weeks after low-dosage roentgen irradiation of the ovaries and pituitary gland. We do not advise irradiation of the pituitary

in the group of cases of primary ovarian failure when the urine contains prolan in excess amount or when the patient is having hot flashes, as such a patient's pituitary gland is making a good physiologic response. Otherwise there seems to be no untoward effect from giving low-dosage roentgen treatments over the pituitary gland and the procedure appears to be beneficial. Increased pituitary function is the normal physiologic response to ovarian failure and often relieves it; therefore it is not unreasonable to stimulate a pituitary gland that has not itself responded.

Emmenin (complex type) will often apparently stimulate the ovaries to greater secretion of hormone and indirectly influence the uterus, and in this way relieve the dysmenorrhea which is associated with partial ovarian failure. Emmenin has been found especially valuable in the treatment of younger women whose dysmenorrhea seems to be on a basis of ovarian dysfunction. It should be begun about the seventh day of the cycle, counting from the first day of the last menstrual period, and should be taken daily until about the twenty-fourth day. Both theelin and emmenin have been very effective in the relief of menstrual headache, and there has seemed to be some relief from grand mal attacks when these have a tendency to occur only with the menses. Acne flaring up with menses has been influenced by theelin and emmenin, and also by injections of a gonadotropic hormone of pregnancy urine (antuitrin S; 200 rat units or 2 c.c. being given every other day for eighteen injections according to Lawrence). As yet it is not known just what histologic or pathologic changes occur in human ovaries on injection of antuitrin S, and therefore much caution should be used in prescribing it. Theelin therapy would seem to be safer. Urticarias which appear to be related to the menses are frequently benefited by theelin therapy. Urticaria seems to be directly related to a lack of estrin in the circulation as it occurs in ovarian hypofunction, either primary or secondary to pituitary failure.

It would seem as if anything which improves ovarian and uterine circulation will help in improving the secretory activity of the ovaries. Vaginal Elliott treatments and diathermy may be at times of benefit when low-dosage roentgen apparatus is not available. Low-dosage roentgen rays probably only pro-

duce their effect by causing a state of congestion in the ovaries. Frequently a combination of treatments helps more than a single type of treatment only. Low-dosage roentgen irradiation of the pituitary gland and ovaries, followed by the administration of emmenin or theelin, seems to give better results than either alone. When theelin therapy is employed, it is better to try and simulate the physiologic cycle and then stop such treatment four or five days before an expected period; otherwise, the period may be postponed and this is psychologically bad for the patient. Continued treatment may not do this, but it very occasionally does.

When one is trying to control severe migraine headaches or grand or petit mal attacks which occur only with the menses, it is better to keep treatment continuous even though there may be some postponement of the period, for two or three months at least. The period is usually only delayed a few days to a week. The continuous use of theelin evidently keeps down pituitary stimulation, so that when it comes it is milder and attacks are not precipitated. The attacks seem to correspond to periods of excess pituitary stimulation, as tests for excess prolan, according to the alcohol precipitation method of Ascheim-Zondek, are positive at these times. No doubt many other factors are present as well, but it appears as if an endocrine imbalance exists and that theelin has some influence on the frequency and severity of the attacks.

In spite of the fact that in these cases of primary ovarian failure one may occasionally get a startling response to low-dosage roentgen therapy after several years of amenorrhea, because one is dealing apparently with a cycle in the uterus as well as in the other glands involved, that is, just a little subnormal, the prognosis with roentgen therapy in cases of primary hypopituitary amenorrhea as a whole, and especially in those in which the amenorrhea is of less than two years' duration, is better than that for cases of primary ovarian amenorrhea. In a recent series of carefully diagnosed cases of primary ovarian amenorrhea of more than six months' duration, only seven of nineteen patients (36.7 per cent) responded to roentgen treatment, which means that periods were reëstablished—in one case after amenorrhea lasting seven years. One woman became pregnant of the four married women who

were treated. Twelve of fifteen (80 per cent) patients of the group with primary pituitary amenorrhea responded to low-dosage roentgen irradiation and thyroid medication, and one of the three married women in this group became pregnant.

Cases in which women have shorter periods of amenorrhea (less than six months) and minor irregularities we class as being those of ovarian dysfunction of the amenorrheic type. In this group thirteen women whose amenorrhea seemed to be related to the pituitary were given low-dosage roentgen treatments. Only one failed to respond and there were four pregnancies among eight married women. One out of nine women with minor menstrual irregularities considered to be due to partial ovarian failure failed to respond and there followed two pregnancies among five married women in this group.

A much higher percentage of improvement was noted among those patients with primary ovarian amenorrhea (more than six months) for whom all types of therapy were tried than among those who had received low-dosage roentgen therapy alone. Fourteen of twenty-one patients (66 per cent) had their periods reestablished. This improvement was brought about by a combination of treatment, giving doses of theelin in oil, 1,000 to 2,000 rat units daily for periods of three weeks in addition to low-dosage roentgen therapy and, when possible, thyroid medication. Theelin in oil has definite value in these cases for it alleviates the symptoms associated with ovarian failure. Injection of theelin in oil has not been tried consistently in the treatment of the hypopituitary amenorrhea in spite of the assumption of some that it might increase the size of the uterus and make it more amenable to subnormal amounts of ovarian hormone in the circulation.

In the group of cases of primary pituitary failure in which patients were treated by all forms of therapy the percentage of reestablished menses after six months of amenorrhea was 69 per cent. As noted before, the majority of patients were treated by thyroid medication and low-dosage roentgen irradiation. The failures in this group occurred when thyroid medication alone was employed or a reduction diet and vitamins alone. Treatment by vitamins alone, while often being sufficient to care for minor menstrual irregularities, is not sufficient to bring on periods after six months of amenorrhea. The same

can be said for thyroid treatment alone, though occasionally it has been very effective.

Of patients with minor irregularities of the primary ovarian type who received all forms of treatment, twenty-nine of thirty-five improved (82 per cent), and of those with minor irregularities of the primary pituitary type, thirteen of sixteen improved (81 per cent). Rapid atrophy of the uterus in the latter group probably is a factor here. It has at times been impossible to overcome this with our treatments. This has led us at the Clinic to treat every woman after three months of amenorrhea if she belongs in this group. Haines and Mussey reported a series of fifty patients with amenorrhea who were treated with desiccated thyroid alone; as a result 58 per cent had normal or nearly normal periods. The average duration of the amenorrhea among those who improved was 9.5 months. Two patients with amenorrhea of four and five years' duration, respectively, had their periods reestablished. No attempt was made in this series to distinguish between primary pituitary and primary ovarian failure.

The metrorrhagic type of menstrual irregularity is probably now the most satisfactory type to treat. The choice of treatment here depends on the age of the patient, the severity of the bleeding and the length of time from the onset of the irregularity. Considering these factors, the most conservative measures possible are always tried out first, especially for younger women. If the metabolic rate is below  $-10$ , it is often very beneficial to give sufficient desiccated thyroid to raise it to  $-8$  or  $-5$  and to hold it there consistently. Patients are then given a diet especially high in vitamins, iron and calcium. The normal weight for the patient is always considered in outlining the diet. If patients cannot drink three glasses of milk a day, calcium lactate is added. This should always be dissolved in some hot liquid, and it is usually given in amounts of 1 drachm (4 c.c.) three times a day. Calcium seems to help at times even when the value for blood calcium is normal. Injections of parathyroid hormone which raises the level of calcium in the blood have been used abroad and have been reported to be of value. In addition, sistomensin (Ciba Company) is still used considerably because it can be given orally and seems to contain sufficient active luteal hormone to be

effective in checking the flow, evidently by changing the endometrium over into the differentiative or secretory type. Sisto-mensin (Ciba Company) contains some estrin also, but it is used in these cases for its content of luteal hormone. It needs to be given in doses of 2 tablets three or four times a day, preferably on an empty stomach. It is best to begin it ten days before an expected period and continue it until the profuse flow is over. If the condition is not controlled in this way, a preparation of luteal hormone, proluton (Schering Corporation) is given intramuscularly. Unless the flow is very severe, ampules containing  $\frac{1}{25}$  rabbit unit are used. One ampule daily for five to seven days will usually suffice to check the flow. By the end of this time the bright red flow will change over into a dark menstrual type and cease after three or four more days. If the periods are fairly regular an ampule of proluton is given every other day for a week prior to the period and for the first five days of the flow. At present proluton is obtainable also in ampules containing  $\frac{1}{8}$  rabbit unit and 1 rabbit unit, but it is not often necessary to use these dosages. Only a very small amount of active luteal hormone seems necessary.

In case of too frequent periods a preparation of luteal hormone given between periods will often postpone the event. If bleeding has been present for several months, there is usually such thickening of the endometrium that the hormone preparation cannot effect a change in it, so it is better to curet it out gently and then, with the aid of the hormone or hormones which are lacking, to attempt to build up a more normal endometrium. Curettage offers a chance to study the endometrium. When both estrogenic and luteal hormones are lacking the endometrium will be atrophic. It is more common for it to be of the hyperplastic type owing to a lack of luteal hormone and an overabundance of estrin.

It is very important in these cases to rule out any blood dyscrasia. At times, when the patient has become markedly anemic, it is necessary to give a blood transfusion. We rely on a diet high in iron rather than giving iron medication such as ferric ammonium citrate which, in our experience, is apt to increase the bleeding. This can be given, when necessary, between periods of bleeding. Severe hemorrhages in these cases are not the rule, and it is often surprising how much and how

long a patient can menstruate without getting markedly anemic. Ordinarily activity does not usually increase the bleeding as the patients themselves will usually declare, and it is best for them to be allowed to carry on their usual activities. Excitement or competitive sport will in many cases initiate or increase the bleeding evidently by stimulating the pituitary gland, and should therefore always be avoided. Rest in bed and ice applied to the lower part of the abdomen, in addition to the calcium and luteal hormone will soon control an increased amount of flowing. There are certain cases in which it would appear as if the dysfunction were primarily pituitary, and in these cases patients respond well to injections of antuitrin S, 200 rat units (2 c.c.) being given every day or every other day during the same period as mentioned for proluton. Great caution must be exercised when this treatment is given, as noted before.

When bleeding persists after all these measures have been tried, intra-uterine radium treatments prove very effective. The dosage depends on the age of the patient. For a patient aged eighteen years, 150 mg. hours is used; for a woman thirty years of age, 350 mg. hours. The effect of the radium may not be apparent for six weeks. After this, menstruation usually ceases for two or three months, during which time the patient regains her strength and overcomes the associated anemia. When the periods return, they tend to be more regular and the duration and amount of flow are more normal. Other methods have been tried, but none has so far been found more effective. With the doses mentioned, no patient in our series ceased menstruating for more than three months, and of twenty-four women treated in this way, twenty-two were having fairly regular and normal periods at the end of one year. The other two were not benefited.

Recently, snake venom has been tried in a small group of cases. Watkins and Mussey have reported their experience with snake venom in seven cases of functional metrorrhagia. The injections were continued for several months, the average time being about eight months, although improvement usually occurred within one or two months after treatment was started. None of the seven patients failed to improve, although one received the venom twice weekly in dose of 1 c.c. for a period

of four and a half months before the menstrual flow returned to what was considered normal. Certain of these metrorrhagic patients also have a tendency to bruise easily, though no definite blood dyscrasia can be demonstrated by any known methods. It would seem as if such patients were particularly suitable for venom therapy.

### CONCLUSIONS

An attempt should be made to classify every functional menstrual irregularity with regard to the glandular dysfunction involved. To do this it is necessary to have in mind a history of the irregularity from the onset and a clear-cut impression of the physical characteristics of the patient and especially of the pelvic organs. Several basal metabolic rates, determinations of the urinary estrin and prolan made at three-day intervals for a month at least and the changes in the endometrial pattern over the same period from biopsy specimens usually fix the diagnosis.

We find that the majority of all functional irregularities fit into two great groups; those secondary to primary pituitary failure and those due to primary ovarian failure. Either an amenorrheic or a metrorrhagic type of irregularity may result from a lack of one or both hormones of the ovary. In primary pituitary failure the basal metabolism is lowered and this seems also to be a complicating factor in the menstrual irregularity. In the treatment in this group, raising the metabolism is a primary consideration but this alone will usually not straighten out many of the irregularities. In addition, stimulation of the pituitary by low-dosage x-ray therapy insured the best results. In primary ovarian failure, it is necessary to improve the condition of the ovaries. The aim is to increase the circulation. This has been done by some form of heat or by low-dosage x-ray therapy. When it is not possible to make the ovaries secrete more hormone it must be supplied to meet the needs of the individual. Primary ovarian failure has associated not only the physical symptoms of faulty function of the dependent accessory organs but all of the nervous and mental phenomena of an unstable vasomotor mechanism. These symptoms are not all directly dependent on a lack of ovarian secretions but to a

compensatory excess of pituitary secretion as they are not present in primary pituitary failure. The good results in the treatment of these cases are so dependent on an accurate diagnosis of the primary gland failure that every means possible to make clear where the deficiency lies and how much deficiency we have to deal with is most essential.

## PROBLEMS OF THE MENOPAUSE AND RELATED THERAPY

DELLA G. DRIPS

---

It was Zondek who first put treatment of the menopause on a logical basis. He studied the blood and urine of women at the climacteric with regard to the amounts of anterior pituitary gonadotropic and ovarian estrogenic hormone present. As a result of these studies he divided the menopause into three periods:

### PERIOD 1

This is the period of more frequent or excessive menstruation, when a higher than normal amount of ovarian estrogenic hormone is found in the blood and urine. It is now considered to be evidence of the failure of development and function of normal corpora lutea. The pituitary stimulus can no longer bring about normal rupture of the follicle and normal luteinization of the granulosa cells. Instead of rupturing, the follicle may become abnormally distended with fluid containing an unusual amount of estrogenic hormone. So-called cystic degeneration of the ovaries occurs in this way. An abnormal amount of estrogenic hormone is secreted into the blood and urine by these cystic follicles. Partial luteinization of the granulosa cells may occur, but such a follicular structure, even though it may become partly luteinized, cannot produce the same amount of luteal hormone as a normal corpus luteum. An imbalance exists between the estrogenic and luteal hormones of the ovaries. This evidence of disturbed function is reflected in the endometrial changes which take place in the uterus. Instead of the normal secretory, late differentiative endometrium of the premenstrual phase, we find an endometrium now known to be representative of luteal failure—a late proliferative type of endometrium which may show cystic

degeneration. The uterus is often found to be larger and softer than normal. This, too, is the result of excessive amounts of estrogenic hormone. In determining the values for estrin in these cases one must remember that the highest values will be obtained about midway between the menstrual periods, as in normally menstruating women, and low values, which seem to contradict the foregoing assumption, may be obtained during the bleeding periods.

**Treatments.**—The treatment of this first period of the climacteric has to do with control of increased menstrual bleeding. As this is only a symptom and may quite as well be evidence of early malignancy of the body of the uterus, curettage is in order to rule this out. If scrapings reveal nothing organically wrong and the endometrium shows the typical proliferative picture, a preparation of luteal hormone may be tried in an effort to control the increased and prolonged flowing. At times, sistomensin (Ciba Company, Inc.) given orally, two tablets three or four times a day, is sufficient. Sistomensin contains both the estrogenic and luteal hormones. It is known that very small amounts of luteal hormone may be sufficient to effect the final premenstrual change in the endometrium. Sistomensin is used in these cases for its content of luteal hormone. Administration must be begun at least a week before the expected menstrual period and be continued through until the flow ceases. Calcium lactate, 1 drachm (3.8 gm.), three times a day after meals, dissolved in some hot liquid, seems to enhance the effect of sistomensin even though the patient's blood calcium is normal. When sistomensin given orally does not suffice, proluton, a standardized preparation of luteal hormone (Schering Corp.) is given intramuscularly. One ampule, containing  $\frac{1}{25}$  rabbit unit, is given daily for five days prior to menstruation and for the first five days of the period when this is deemed necessary. Ampules containing  $\frac{1}{3}$  and 1 rabbit unit of proluton per cubic centimeter are also available and can be used when necessary. Preparations of ergot do not help much. If menorrhagia continues for more than five or six months, and if the hormone preparations do not suffice and the patient's hemoglobin begins to drop, radiotherapy is used. Women of this age are urged to have sufficient intra-uterine radium or pelvic roentgen treatments to stop the menses.

## PERIOD 2

This is the period of vasomotor disturbances. During this period there is further evidence of ovarian failure. There are fewer granulosa cells of the follicles to respond to pituitary stimulation. A decreasing amount of estrogenic hormone is secreted by the follicle. The uterine endometrium reaches only an early proliferative phase, or may show no evidence of regeneration. The uterus is found to be smaller than normal. The menses become farther apart and less in amount, finally ceasing altogether. A rhythm is usually maintained to the end. The menses will occur, instead of every twenty-eight days, at multiples of this interval—every two, three or four months. This is significant in that it emphasizes bleeding which occurs at irregular intervals as denoting some organic abnormality. The vasomotor disturbances reach their height during this period. They may be present for some time before the menses cease tending to occur at the midinterval and during menstruation. It is during this period also that the blood and urine of the patient begin to show an excess of anterior pituitary hormone, which increases in amount with the ovarian failure. The amount of estrin in the blood and urine decreases.

**Symptoms.**—The increased menstrual molimina at this age are often most distressing. Women who have never had any soreness in the breasts prior to menstruation will complain of it during this late period of their menstrual life. They can often predict the onset of a menstruation seven to ten days after soreness is present. ¶

Another characteristic complaint is headache of the migraine type, which comes either just before, during, or after menstruation. If the patient has always had headache with the menses, it becomes much aggravated. Many women have headaches only during this age period. After the menses cease, most women are free of this migrainous type of headache.

Patients also complain of nervous instability; they get annoyed easily, become fatigued easily, and are easily stimulated or depressed for a week or so before their menstrual periods. Many women have increased discomfort with the menses as these become scantier and farther apart.

Probably, for the majority of women, this age period be-

degeneration. The uterus is often found to be larger and softer than normal. This, too, is the result of excessive amounts of estrogenic hormone. In determining the values for estrin in these cases one must remember that the highest values will be obtained about midway between the menstrual periods, as in normally menstruating women, and low values, which seem to contradict the foregoing assumption, may be obtained during the bleeding periods.

**Treatments.**—The treatment of this first period of the climacteric has to do with control of increased menstrual bleeding. As this is only a symptom and may quite as well be evidence of early malignancy of the body of the uterus, curettage is in order to rule this out. If scrapings reveal nothing organically wrong and the endometrium shows the typical proliferative picture, a preparation of luteal hormone may be tried in an effort to control the increased and prolonged flowing. At times, sistomensin (Ciba Company, Inc.) given orally, two tablets three or four times a day, is sufficient. Sistomensin contains both the estrogenic and luteal hormones. It is known that very small amounts of luteal hormone may be sufficient to effect the final premenstrual change in the endometrium. Sistomensin is used in these cases for its content of luteal hormone. Administration must be begun at least a week before the expected menstrual period and be continued through until the flow ceases. Calcium lactate, 1 drachm (3.8 gm.), three times a day after meals, dissolved in some hot liquid, seems to enhance the effect of sistomensin even though the patient's blood calcium is normal. When sistomensin given orally does not suffice, proluton, a standardized preparation of luteal hormone (Schering Corp.) is given intramuscularly. One ampule, containing  $\frac{1}{25}$  rabbit unit, is given daily for five days prior to menstruation and for the first five days of the period when this is deemed necessary. Ampules containing  $\frac{1}{5}$  and 1 rabbit unit of proluton per cubic centimeter are also available and can be used when necessary. Preparations of ergot do not help much. If menorrhagia continues for more than five or six months, and if the hormone preparations do not suffice and the patient's hemoglobin begins to drop, radiotherapy is used. Women of this age are urged to have sufficient intra-uterine radium or pelvic roentgen treatments to stop the menses.

## PERIOD 2

This is the period of vasomotor disturbances. During this period there is further evidence of ovarian failure. There are fewer granulosa cells of the follicles to respond to pituitary stimulation. A decreasing amount of estrogenic hormone is secreted by the follicle. The uterine endometrium reaches only an early proliferative phase, or may show no evidence of regeneration. The uterus is found to be smaller than normal. The menses become farther apart and less in amount, finally ceasing altogether. A rhythm is usually maintained to the end. The menses will occur, instead of every twenty-eight days, at multiples of this interval—every two, three or four months. This is significant in that it emphasizes bleeding which occurs at irregular intervals as denoting some organic abnormality. The vasomotor disturbances reach their height during this period. They may be present for some time before the menses cease tending to occur at the midinterval and during menstruation. It is during this period also that the blood and urine of the patient begin to show an excess of anterior pituitary hormone, which increases in amount with the ovarian failure. The amount of estrin in the blood and urine decreases.

**Symptoms.**—The increased menstrual molimina at this age are often most distressing. Women who have never had any soreness in the breasts prior to menstruation will complain of it during this late period of their menstrual life. They can often predict the onset of a menstruation seven to ten days after soreness is present.

Another characteristic complaint is headache of the migraine type, which comes either just before, during, or after menstruation. If the patient has always had headache with the menses, it becomes much aggravated. Many women have headaches only during this age period. After the menses cease, most women are free of this migrainous type of headache.

Patients also complain of nervous instability; they get annoyed easily, become fatigued easily, and are easily stimulated or depressed for a week or so before their menstrual periods. Many women have increased discomfort with the menses as these become scantier and farther apart.

Probably, for the majority of women, this age period be-

fore the final cessation of the menses is the most distressing one of the whole climacteric. Partial ovarian failure and compensatory, excess pituitary function lead to complaints of a physical nature, such as soreness of the breasts, headache, aching of the back and thighs and dysmenorrhea, and these, together with the beginning mild vasomotor disturbances are repeated with each menstrual period and are incapacitating and exasperating.

When the menses finally cease, vasomotor disturbances often become more severe for a time, usually for six to eight months, and then either subside entirely or continue to come and go with varying severity for several years. There may be some ovarian function sufficient to bring on these rhythmic symptoms for some months after any external evidence of menstruation is present, as studies of the hormones in blood and urine during this period have proved.

It would not seem amiss here to describe in detail what is meant by a "hot flash." Many clinicians are not familiar with the sensations that accompany such a vasomotor phenomenon. German physicians term the phenomenon a "vasomotor wave." The patient most often notices the sensation first in the epigastrium. This is the aura, and with it comes to some a feeling of oppression as though something were going to happen, or a feeling of light-headedness or faintness; a peristaltic movement of the bowel is often sensed and may be followed by the passage of gas from the rectum. At the same time the wave seems to rise upward through the chest to the neck and head. The patient may be conscious of palpitation of the heart or of a sense of air hunger, and take one or two deep breaths; her head feels as if it were going to burst. Then the sense of heat comes, first to the face and neck, next spreading to all parts of the body; finally moisture is felt in the palms, soles, axillæ and about the trunk. At times sweating may be so profuse as to drench the undergarments or make a change of night clothes imperative. Any or all of these sensations may be minimized or exaggerated in the individual case. Zondek stated that with the most intense stimulation there may be associated alterations in the psyche: depression, increased irritability, restlessness, impairment of memory, easy mental fatigue and many other symptoms. He has explained the phenomenon as originating

in the vasomotor center of the brain. A stimulus is sent to the splanchnic region, this entire region of the abdomen then contracting and a large amount of blood being forced into the peripheral vessels. As the result of such a displacement of blood there are feelings of faintness, palpitation, oppression, air-hunger and anxiety. Thus the subjective sensations have an objective explanation. The regular recurrence of vasomotor waves at intervals, day or night, is often remarkable. The patient's sleep is very much disturbed and a state of severe fatigue often ensues.

It is not surprising that a woman who experiences one of these vasomotor waves for the first time becomes much concerned. Her fear becomes directed usually to one of the vital organs involved, depending on which location the stimulus received is the strongest. One woman will complain of gastrointestinal sensations, of a "queer feeling in the epigastrium," "nausea," "gas," "bowel-spasm," or "a little convulsion of the bowel"; another will complain of "palpitation" and "shortness of breath"; still others of a "bursting fullness" in the head. Perhaps palpitation makes the patient "heart conscious" for the first time, and she immediately begins to worry about heart trouble. She goes to a doctor and complains of a rapid and irregular pulse, palpitation and fluttering; it keeps her awake at night. She is short of breath on exertion. She may not mention the other sensations of the vasomotor wave, her mind being too fixed on her heart. The vasomotor waves may even have subsided and left only the cardiac neurosis of the menopause. Many neuroses of similar origin supervene during this period. Perhaps the most unfortunate victims are those with whom sweating is the most prominent feature of the wave. These women will be seen in midsummer wearing woollen garments and even furs because they "chill so" after sweating. Several such patients say they have ceased to have any sensation of heat: all they complain of is "drenching perspiration followed by great chilliness," which occurs at regular intervals.

In a majority of the cases in which women suffer from these vasomotor disturbances a morning specimen of urine will reveal an excess of prolactin or anterior pituitary gonadotropic hormone; 60 c.c. of urine only are required. This may be injected directly after shaking with ether to get rid of the estrin. How-

ever, many more positive results are obtained by an alcohol precipitation method. The prolactin is precipitated with alcohol and the precipitate is injected into white rats twenty-one days old. These rats, with their control, a litter mate, are killed 100 hours after the first injection is given and the ovaries and uteri are observed grossly and weighed. The ovaries are then embedded in paraffin, and cut, stained and observed for evidence of follicle stimulation or luteinization. When the latter is present, we consider the hormone to be present in greater amount than when follicle stimulation only is observed. If a positive result is obtained with 3 c.c. of unconcentrated urine, 330 units of prolactin are present in a liter of the patient's urine. When the urine is concentrated five times by the alcohol concentration method, 66 units are present. It is not necessary to estimate the amount of prolactin exactly, although two or three dilutions give a better idea of the excess present. All that is necessary is to determine if prolactin is present in excess amounts. It is well to determine the value for estrin in a twenty-four hour specimen of urine about the same time as the morning specimen of prolactin is obtained and, if possible, to obtain a twenty-four hour specimen of urine weekly for the determination of estrin to see if any ovarian function is still present. In cases in which patients have had a fairly recent menstrual period the test for excess prolactin may be negative, for we observe them at a time in the cycle when estrin is present in sufficient amounts to suppress pituitary function. If several determinations of urinary prolactin are made, one will be sure to get a test positive for excess prolactin at some time during the monthly cycle. This will fairly well correspond to the period when estrin is lowest or absent, and it is during this period that the vasomotor disturbances are present.

In women suffering with vasomotor disturbances long after ovarian function has ceased, as evidenced by atrophy of the genitals and negative estrin tests, a test for excess prolactin should be positive if pituitary hyperfunction still exists. The test is all important in these cases as only those who show excess prolactin seems to respond to hormone therapy. It is our custom to repeat a negative test. It would seem quite probable that in the other cases, the nervous system has continued a vicious

habit of vasomotor waves and for these patients, psychotherapy and sedatives accomplish more.

In the past two years we have seen eighty-four women at the Clinic who complained of hot flashes or symptoms that were considered to be of functional origin and possibly related to the menopausal syndrome. Fifty-nine of these women were having hot flashes of from grades 2 to 4. With the exception of four women, all were more than forty years of age; the oldest was seventy-one. Of the four women less than forty, three had had their ovaries removed for tumors; one woman of

Fig. 52.—Results of tests for excess prolactin: Outlined squares show number of patients studied (59), shaded squares show number for whom the urine was positive for excess prolactin (34).

thirty-five years had had spontaneous cessation of periods at the age of twenty-eight. Of the women more than forty years of age, five were still having their menses. Of these fifty-nine women who were having severe, hot flashes, the urine of thirty-four (57.6 per cent) gave a positive test for excess prolactin (Fig. 52).

This study substantiates the findings of others that the majority of women with vasomotor disturbances sufficient to bring them to the physician belong to the second period of the climacteric, the period when the menses are ceasing, and this is the period when the greater number show excess prolactin.

Perhaps, had we used a method of extraction that would have precipitated more prolان, or tried to do a quantitative determination, we would have found a much larger number of women whose urine showed more than a normal amount. By the Aschheim-Zondek alcohol concentration method which we used, a positive test is evidence of the presence of at least 66+ units per liter. The normal amount would perhaps not exceed 16 units.

Österreicher found 50 per cent of his cases positive for 330 units, 60 per cent positive for from 110 to 80 units and 92 per cent positive for 55 units. The urine of ninety-six of 105 women, fifty to ninety-three years of age, reacted positively for excess prolان. Several examinations of the urine were made in some of these cases before a positive test was obtained. Österreicher was able to demonstrate luteinizing hormone in 8 per cent of his cases. Of 105 old women, seven showed it, and of five who had been castrated, two showed it, four and twelve years after gastration—typical yellow bodies next to ripe follicles. He found blood points in only one case, that of a woman who had cardiac decompensation. The urine in this case was concentrated ten times. The same patient half a year previously, before decompensation had taken place, had been negative on five-fold concentration of the urine.

The oldest woman in the group we studied came to the Clinic primarily because of dizziness and various sensations of pressure and tension in her head. These were taken to be arteriosclerotic manifestations. She stated that she had had hot flashes for thirty years since spontaneous menopause at the age of forty. A morning specimen of urine was obtained and was found to contain excess prolان. The cross section of an infantile rat's ovary (Fig. 53, *a*) shows the follicle stimulation we consider as an evidence of the presence of excess prolان. Another woman, fifty-eight years of age, the mother of eight children, came to the Clinic primarily because of nervousness, which she stated made her have palpitation, weakness, faintness and blackness before her eyes, cold chills and shaking spells. Such a train of functional symptoms had developed that her home physician and family had considered placing her in a hospital for nervous and mental diseases. Her periods had ceased ten years before, spontaneously. Her urine was

strongly positive for excess prolactin (Fig. 53, *b*) which proved that many of her symptoms could be explained on a physiologic basis.

Another woman, fifty-four years of age, reported at the Clinic in June, 1935. She had had her right ovary removed twenty-eight years before, elsewhere, because of a cyst. Her menses ceased at the age of forty-six. Following this she stated that she began having attacks of epigastric pain which sometimes came on at or immediately before, and at other

Fig. 53 —*a* and *b*, Cross sections of infantile rats' ovaries, showing follicle stimulation (case 1 and 2).

times an hour or more before, meals and also awakened her at night. This history was fairly clear for ulcer. On physical examination she was found to have a large ovarian cyst, and roentgenologic examination of her stomach revealed a small gastric ulcer near the lesser curvature, with hour-glass deformity. She was operated on June 12, 1935. A large cystic tumor was found lying between the folds of the left broad ligament. There was no evidence of a left ovary. On July 5, 1935, partial gastrectomy was performed for gastric ulcer, a posterior Polya type of anastomosis being made. The patient

returned to the Clinic February 5, 1936. She came chiefly because she had been told to return for reëxamination of her stomach condition. She stated that since the operation she had had attacks during which she suffered from dizziness, weakness, palpitation, a sense of warmth, nausea, vomiting and sweating, the entire attack lasting about five minutes and being associated with considerable nervousness. She said she had some epigastric pain during these attacks, which was

Fig. 54.—Marked excess of prolan as evidenced by corpora lutea in the ovary of an infantile rat (case 3).

situated over the site of the incision, but that this pain was not nearly as severe as before operation. At first she gave the impression that these attacks occurred after meals, and it was felt that she might be suffering from a widespread sympathetic reaction resulting from rapid dilatation of the jejunum. While she was under observation the attacks were timed and they were found not to occur particularly after eating; a note was then made that there were apparently other triggers. No clear history of ulcer could be elicited. The morning speci-

men of urine revealed a marked excess of prolactin, as corpora lutea were present in the ovaries of the experimental animals (Fig. 54). Before the report of the prolactin test was obtained the patient was given an injection of 2,000 International units of theelin-in-oil every other day for three times; she did not improve and was sent home, phenobarbital being prescribed for her. This medication has helped her some. After the report of the prolactin test it was evident that the three ampules of theelin were not sufficient to produce any amelioration of symptoms.

Twenty-seven of these eighty-four women in the climacteric came for bizarre complaints which had come on since the cessation of their menses but they were not complaining of hot flashes. Five of these women had excess prolactin in their urine. Estrogenic hormone was advised in these cases in similar dosage to that given to patients with hot flashes. All of these five women reported they were better.

Much has been written about the gain in weight that takes place after cessation of the menses. No doubt some unknown endocrine factor at work is partly responsible for this. Marinus has recently suggested that the obesity is due to a nervous hunger; they may become hungry faster owing to the faster emptying time of the stomach and increased peristalsis. This may be an effect of excess secretory function of the posterior lobe of the pituitary body. Women state that they have less trouble with constipation, and some even have frequent, loose stools during the climacteric period, probably, also, owing to increased activity of the posterior lobe. In some cases nails and hair grow more rapidly during this period, which suggests an increase in the secretory function of the cells producing the growth hormone. It would appear probable that there is some excess secretion of all the pituitary hormones during this period.

**Treatment.**—Treatment of the second period of the menopause is directed chiefly toward control of the distressing symptoms associated with ovarian failure, particularly vasomotor disturbances. These may have been present for several months before any menstrual periods are skipped. They seem to occur at two times in the cycle, about the midinterval and during the period itself, when they are often most disturbing.

It is known that these are the two times in the cycle when prolactin is present in greatest amounts in the urine; estrin is lowest during menstruation.

Before treatment is begun, a morning specimen of urine is tested for excess prolactin. The character of the vaginal smear is also studied. This has proved a valuable aid in therapy as it is possible to tell by vaginal smears, according to the method of Papanicolaou, when treatment has become effective. A subsidence of symptoms should come with the presence of the typical cornified or leukopenic smear in the vagina.

In the ordinary case treatment is begun with a daily injection of 1 c.c., 1,000 International units, of theelin-in-oil (Parke, Davis and Company). The patient is told that she will not notice much change in her symptoms for from six to ten days, which time is necessary to bring about a suppression of pituitary function. It is probable that there may be an ovarian hormone the lack of which may be directly responsible for the vasomotor disturbances. Marinus reported, at the recent session of the American Association for the Advancement of Science in St. Louis (January, 1936), that subcutaneous injections of a substance of the whole ovary would stop hot flashes immediately and the effect would last forty-eight hours. I have had no experience with this substance.

If the patient is much fatigued from loss of sleep as a result of the frequent occurrence of hot flashes and sweats at night, she is given  $1\frac{1}{2}$  to 3 grains (0.1 to 0.2 gm.) of amytal at bedtime after a warm relaxing bath. She is told to avoid heavy bed clothing and to sleep in a cool but not a cold room out of a draught. Administration of amytal is continued until the theelin begins to produce its effect; it is then easily discontinued.

In cases in which the gastro-intestinal symptoms are prominent, small doses of phenobarbital, for example  $\frac{1}{2}$  grain (0.03 gm.) three times a day after meals, may need to be given for a time with the theelin. A smooth, easily digested diet, and when nausea is present frequent feedings, add much to the patient's comfort. Coffee, tobacco and alcohol should be avoided; they may give a temporary sense of comfort, but the vasomotor mechanism is made constantly more unstable by any undue stimulation.

After twelve to fourteen injections of 1,000 rat units of theelin-in-oil have been given, it is often possible to reduce the daily dose or to skip a day. Whenever the amount of theelin is reduced, reduction should be very gradual so as not to re-stimulate the pituitary. It is best to carry the patient for several weeks on at least three injections a week before cutting down further, and then, if possible, to switch over to an oral preparation, the one most familiar to me being progynon (Schering Corp.). Two tablets (45 rat units each) three times a day, before meals, are usually necessary to control vasomotor disturbances. The symptoms of many women not controlled with the 1,000 units daily of theelin-in-oil are easily controlled with 2,000 International units. After they have had this for twelve days and their symptoms have subsided, the dose is very gradually reduced.

For women who are still menstruating but who are having disagreeable vasomotor disturbances this treatment is kept up regularly also. It has not seemed to make much difference about the regularity of menses. The dose of theelin necessary to control hot flashes is probably not sufficient to postpone menstruation. Larger doses will do this at times, and when large doses are necessary for young women to control disagreeable molimina, it is always best to stop the administration of theelin four days prior to the regular time of onset of the period. Many women during the menopause need to continue taking theelin for a year or two years. They may cease having symptoms and go without treatment for a time, when treatment will have to be resumed and theelin again will be required in daily doses for a time. Patients are switched over to progynon by mouth as soon as it is felt it will carry them.

Certain women suffer during this second period rather long-continued phases of depression; as they express it, they usually feel very tired and depressed, are fearful and tend to worry about trifles. The usual accustomed work looks big to them and they dread to undertake it; they even hate to make any effort to be social. they are irritable and sensitive, emotionally unstable. cry easily and occasionally have nervous "spells" when they feel as if they were losing their minds; they "can't think." or they "shake all over and have to go to bed." Attacks of depression may alternate with periods of feeling very elated

and stimulated. They are as conscious of this false sense of stimulation as they are of depression. These states are usually present while the vasomotor disturbances are present. As has been noted before, however, the psychic states may impress the patient more than the vasomotor phenomena and be more emphasized. Theelin therapy improves this mental state very much. Coincidental with treatment sufficient to produce the vaginal reaction, a sense of well-being and of self-confidence and stability returns.

Certain skin manifestations are prone to occur during the menopause which also appear to be helped by theelin therapy: urticaria, angioneurotic edema and atopic eczema. The urticarias are apparently directly related to estrin deficiency and not to excess pituitary secretion, as they occur in young women with ovarian deficiency and amenorrhea when not even normal amounts of prolan can be detected in the urine.

Asthmatic attacks and epileptiform seizures beginning at this age period may also be related to an endocrine imbalance. Not enough endocrine studies have as yet been made in these cases to arrive at any conclusion as to what hormone deficiency is responsible. There are many bizarre symptoms which women complain of during this period that are at times associated and at times unassociated with vasomotor waves, such as continuous parietal or occipital headaches, pressure in the head, sinking spells, disturbances of equilibrium and aching in the lower part of the back and in the thighs. If no organic cause is found to account for these, we at the Clinic consider theelin therapy, provided the test for excess urinary prolan is positive.

Patients who have hypertension seem to need larger doses of theelin to control the vasomotor symptoms; on the other hand, theelin seems in these cases to have a beneficial effect on the blood pressure. Hypertension frequently begins to develop in this age period, as has been noted by Schaeffer, and theelin helps to reduce it.

Occasionally one finds women who have continued to have these vasomotor disturbances for an unusually long time. Urinary prolan is not in excess; perhaps not even normal amounts can be detected. Metabolic rates are lower than normal. Giving these women desiccated thyroid gland has made

them feel better, and sleep and eat better, and after a time the hot flashes have ceased. It would appear as if the pituitary had ceased its overfunctioning and was reacting with less than normal function, reducing metabolism and inducing fatigue, and as if the nervous system of the fatigued patient had continued to respond to stimuli keeping up the vasomotor waves.

Much advice in a general way is given these women in the climacteric. They are advised to spend a great deal of time in the open air, to take regular exercise and to keep to their usual routine of work or business. The woman who has time to observe the exact time of each flash, so that she can tell you just how many she had during the day, must be warned that she is allowing the impressions made on her conscious mind to sink too deeply, making nerve paths which may become too fixed and making the habit persist after the glandular stimulation has ceased. It is advisable, therefore, to let the process go on as unconsciously as possible. The woman, then, who is forced to keep busy and to forget herself is the more fortunate one; however, she must find more time for frequent periods of relaxation and rest to compensate for her disturbed rest at night or complaints related to chronic fatigue will develop. Currier once wrote, "All that tends to develop and strengthen the physical part of woman, to render her insensitive to the ordinary ills of life, to make her forgetful of self, is favorable to a normal menopause."

### PERIOD 3

Period 3 is the period of atrophic change in the accessory organs which is brought about by a continued lack of ovarian estrogenic hormone. This hormone is found to be absent in the blood and urine with the usual test methods. Conditions such as pruritus vulvæ, kraurosis vulvæ and atrophic vaginitis may be present. Hot flashes may have subsided, depending on the subsidence of anterior pituitary function, with overproduction of gonadotropic hormone. The blood and urine may still show an excess of this hormone.

**Symptoms.**—To some women this period brings more actual distress and discomfort than any preceding period. Their symptoms are related to atrophic changes about the vulva or

the vagina, or both. The complaint which brings the greatest number of patients to the physician in the early stage of atrophy is itching. Burning is associated if friction and a resulting inflammation of the skin have ensued. Itching is extremely likely to begin in the fourchet or in the skin of the perineum, and for some time it may remain localized in these regions, or it may spread and involve the labia and clitoris and extend posteriorly about the anus. The inflammatory process, if present at all, is most marked at the beginning. The entire vulva may be swollen, the folds standing out prominently. The skin appears stretched, glistening and pale. The shrivelling-up process then begins to be evident. The labia minora becomes smaller, the vaginal orifice becomes greatly narrowed, and the mucous membrane appears very pale and even white; at times it may appear very white and thick and almost leathery. To this shrivelling-up process has been given the name "kraurosis vulvæ." These changes may all be considered entirely physiological, the result of a loss of ovarian function.

**Treatment.**—During the third period of the climacteric, treatment is related to the symptoms associated with atrophy of the genitalia. The itching associated with the onset of the atrophy often responds to injections of theelin-in-oil. Usually, to influence this condition of the skin and mucous membrane, it is necessary to begin with larger doses of theelin. Two thousand International units are given daily and are continued until the full effect of treatment is noted in the vaginal smear. This usually requires ten to twelve injections, and injections must usually be continued three times a week for from four to six weeks. It is frequently possible to see grossly a change in the mucous membrane of the vagina and vulva. The mucous membrane changes from white or pale-pink to bluish-red, and from a dry to a moist texture, and the symptoms subside.

The first advice given the patient should be in the form of a warning regarding scratching or rubbing the parts: soap should not be used on them. Often, to allay a paroxysm of itching, soda water (about 5 per cent sodium bicarbonate) is applied as hot as it can be borne by bathing the parts or by sponging and then not drying the skin. The cooling effect of evaporation of the fluid causes vasoconstriction. Fantus has called attention to this. If burning and inflammation are

present, packs soaked in an 8 per cent solution of aluminum subacetate, 1:16 parts of water, is helpful. Oily lotions, such as olive oil and lime water or Schamberg's lotion,<sup>1</sup> have seemed to relieve many patients. The lotion is applied nightly, and oftener if necessary.

Leukoplakic areas may develop on this chronic atrophic process; these are discrete plaques involving the inner surfaces of the labia majora and labia minora, fourchet or around the clitoris, and they may cause the most intense itching. They are grayish, and there is definite thickening of the skin or mucous membrane; fissures or ulcerations may occur about these areas. When these leukoplakia areas are present, it would seem unwise to resort to theelin therapy as they are precancerous lesions. Surgery, either excision or vulvectomy, is the only safe treatment. Adair and Davis have recently emphasized this.

A patient may complain of burning and of a feeling of fullness in the vagina. This may or may not be associated with sufficient discharge to make her conscious of it. On inspection the vaginal mucous membrane appears thin, glistening and reddened; one may see the vagina peppered with red spots, 1 or 2 mm. in diameter, patchy areas of redness, or it may be diffusely reddened. The fornices may be closed by adhesions of the cervical lips to the vaginal walls. Contractures of the vagina may be present. Small punctate ulcerations of the mucous membrane may be seen in the upper part of the vagina. When considerable redness is present, evidence of a superimposed acute inflammation, the discharge may be quite purulent; otherwise the discharge is usually milky. Some gross blood may be present in the discharge or the discharge may appear pinkish. The discharge is not mucoid unless an old chronic cervicitis is also present. This atrophic type of vaginitis also responds very well to theelin therapy. When vaginitis alone is present and there are no vulvar symptoms, 1,000 International units of theelin are given daily until the effect of treatment is noted in the vaginal smear. It is well to give some mild local treatment during the first week to help clear up the coexisting infection. *Trichomonas* are often found

<sup>1</sup>Menthol 0.6; phenol 4.0; oil olive 120.0; liq. calcis 120.0, and pv. zinc oxide 200.

in a hanging drop of the fresh smear. Bacteria are plentiful. Painting all of the vaginal and cervical mucous membrane with a watery solution of gentian violet 1:500 will help greatly to clear up the infection present. Keeping the vagina packed with kaolin (Merck's) to absorb the secretions facilitates this and this drying out process is often sufficient to rid the vagina of the *Trichomonas*. It is surprising how quickly the vaginitis and the corresponding symptoms will clear up. The injections of theelin should be kept up from four to six weeks, three times a week after the first ten to twelve days according to the procedure outlined by Davis. Treatment can then be discontinued and the patient may have no further trouble. If the symptoms recur, another course of treatments can be given. After the vaginitis has cleared up, it is easier to tell whether any chronic cervicitis is present. A light cautery will take care of this.

It is wise to tell women suffering from this atrophic or senile type of vaginitis that the condition may recur and that another course of treatment may be necessary. It is well to warn them also that when any blood is present in the discharge, a physician should be consulted so that a decision can be made as to where the blood is coming from.

Thus each of the three periods of the menopause has its own problems and specific therapy. During the first period the failure of the ovaries to produce normal corpora lutea brings about an increase in the amount and duration of the menstrual flow. If curettage reveals only the characteristic endometrial picture, luteal hormone will frequently control the bleeding. If it does not, removal of the uterus or a menopause dose of radium or roentgen rays is in order. During the second period, that of the vasomotor disturbances, when the pituitary is hyperfunctioning as evidenced by the excess prolactin found in the urine, the estrogenic hormone of the ovaries given in sufficient dosage will suppress the pituitary function and thereby allay the patient's symptoms. During the third period, when atrophy of the external genitals consequent to an absence of ovarian secretions is marked enough to produce symptoms of itching and inflammation, estrogenic hormone will restore the mucous membrane to a condition corresponding to the follicular phase of the menstrual cycle, which is of definite therapeutic benefit to the patient.

## CLINIC OF DR. E. J. G. BEARDSLEY

JEFFERSON MEDICAL COLLEGE

---

### SIMPLICITY IN THE DIAGNOSIS OF CARDIOVASCULAR DISEASES

**Introduction.**—The inauguration of still another college session in Jefferson's historic clinic serves to emphasize the truth of the radio slogan, "Time Marches On."

Any physician who has been actively connected with a clinical branch of a medical school's curriculum for over thirty years has had both time and opportunity to develop firm convictions regarding how he may prove most helpful to students, undergraduate or graduate.

In any clinic, well advanced in its second century of usefulness, almost exclusively devoted to the education of undergraduate students and to the interests of the sick poor, there are bound to exist inspiring traditions and time-approved clinical methods of investigation and study.

One tradition we have at Jefferson, ancient as the school's origin, concerns the firm belief of the founders that the status of a nation's medical profession can best be judged by the character, education, training and skill of the general practitioner of medicine.

We believe today, as the founders of the Jefferson Medical College believed in the early portion of the nineteenth century, that our school can serve no higher or more useful purpose than to provide a sound general medical education, with proper emphasis upon the essential foundations for a vital and comprehensive medical philosophy and with even greater insistence upon intensive clinical instruction for those who will, by these measures, be properly prepared to become general practitioners of medicine.

We are convinced, by observation and long experience, that a well-educated and conscientiously-trained general prac-

itioner of medicine of the right type is the most generally useful, although, unfortunately, not the most usually appreciated physician in the world today.

Whether a physician continues throughout his professional life as a general practitioner or whether he, later, enters a specialty, the discipline and training in general practice, providing it has been of the progressive, enlightening and inspiring variety, cannot but have made it possible for him to have been particularly useful to his patients.

It is exceptional to observe a specialist who has not enjoyed the broadening experience of general practice, whose professional judgment is as sound as one who has been aided by such a helpful experience.

The founders of our school believed that superior qualities of character, combined with such helpful essentials as natural aptitude for the duties and responsibilities of the medical profession, the possession of "the saving grace of common sense," intellectual honesty and, not least in importance, the possession by the candidate of a sincere and altruistic interest in helping those in trouble comprise far more important qualifications for an individual entering and remaining in the medical profession than the possession by the candidate of brilliance of intellect, superior scholastic marks and exaggerated self-interest.

It is true that the founders lived in a different century than the present but who can deny that the sick, in any century, need the services of kind and skilled physicians of integrity and honor whose chief object is to serve, as best they may, the interests of their patients.

We believe today, as the founders of this school believed long ago, that the profession of medicine is an art that is firmly based upon a knowledge of science.

We are convinced that medicine can never become an exact science, if for no other reason than because the individual patient is unique.

The arrangement and potentialities of the many chromosomes that comprise each embryo produces an individual unlike any individual who ever lived and, likewise, unlike any who now live or will live in the future.

Each patient's reaction to life, to environment, to health,

to disease and to drugs and other therapy are all, far beyond our present knowledge and understanding, uniquely individualistic.

It is, fortunately, true that medicine has a sound foundation in science, its methods and procedures are improved and greatly advanced by science and by the improvements in scientific methods but the everyday practice of medicine will ever be, as in the near and remote past, an empirical art.

The more rounded a student's education before entering the medical school the more fortunate both the student and his future patients unless it be, as sometimes happens, that a medical neophyte mistakenly magnifies the importance of book knowledge and fails to interest himself in human beings whom he, later, wishes both to understand and to serve.

It is traditional, unfortunately, that the word "study" usually indicates to a medical student, undergraduate or graduate, intimate contact with the contents of a book but, if the truth was known and fully appreciated, it would be to any student's advantage if he could spend more time in intimately studying and obtaining an extensive first-hand knowledge of normal, average, well people.

It is to be remembered that, although much time has elapsed since Rousseau, in 1754, expressed the opinion that "the most useful and least advanced of human knowledge seems to me to be of man himself" conditions regarding an intimate and comprehensive knowledge of human nature by members of the medical profession have changed all too little.

It is a serious reflection upon our lack of vision as teachers in medical schools that charlatans and other pseudomedical cultists frequently exhibit evidence of far more profound understanding of human nature, in its infinite varieties, than do many classically educated and so-termed "scientifically" trained physicians.

Certain physicians of limited vision and unworthy of the best traditions of their profession are inclined to view their patients as pathologic material provided by nature for the economic improvement of the doctor and not as unfortunate human beings who are in trouble.

It is surprising that, through all the centuries, so few medical curricula have emphasized the importance to the medical

student and physician of the future of an intimate knowledge and perfect understanding of the psychology of men, women and children in health as well as in their periods of illness.

The medical student, undergraduate or graduate, who desires to prove most helpful to his patients will do well to remember that the patient, in the majority of instances, is much more difficult to understand than is the disease process that affects him.

One cannot, I think, emphasize too vigorously the wisdom, even the practical necessity, for early acquiring and continuing to acquire throughout life, an intimate knowledge and understanding of varying types of individuals, living under different conditions of environment, in health, as an all important training for the comprehension and helpful understanding of similar individuals when they become ill.

The more intimate and extensive one's understanding of human nature the easier it becomes to understand the psyche and the peculiarities and idiosyncrasies of those individuals who are ill.

Medical curricula, unfortunately, are not influenced by the experiences of recent graduates who are in a position to fully realize the weaknesses and deficiencies of the plan of education and training that was provided them. Such graduates could, undoubtedly, give helpful suggestions for improvement in the courses of study and training but medical curricula are, as a rule, traditional relics from the remote past that change little with the years and are influenced only remotely by the experience, in practice, of the school's graduates.

Before a medical student arrives at his "clinical years" he is fortunate who has acquired, by heredity, by environmental contacts and by general observations, a philosophical point of view that can be, if occasion arises, altered as he increases his experience and grows in wisdom.

The observing student will soon learn that, although political orators may declare with winged words that men are born free and equal, no naturalist or physician believes this to be true of either physical, emotional or intellectual characteristics.

That wise physician and sound medical philosopher, Oliver Wendell Holmes, expressed an incontrovertible truth when he

stated that, "man is an omnibus in which all his ancestors ride."

It is an amazing evidence of the intellectual myopia that sometimes afflicts medical teachers and the medical profession's leaders that, through the centuries, so relatively little attention has been directed to the paramount influence of hereditary factors as vitally influencing health, happiness, and disease.

Hereditary influences are the most important single factor influencing a life in health and it is, probably, a far more important determinant than we, at present, understand in disease prevention and production.

Any one physician's active professional life permits him to see and study but two or, possibly, three generations of individuals, sick and well, and by the time he has become thoroughly acquainted with the ancestral characteristics, susceptibilities, resistance and peculiarities of his patients, Charon's Ferry awaits him.

It is difficult, if not impossible, to efficiently transmit to others the patiently and, all too slowly, acquired information regarding observed hereditary factors and influences that have been obtained through a professional lifetime.

Any physician who, from his early years in clinical experience, resolved to faithfully study and systematically record the observed influence of hereditary factors influencing health and disease would, in all probability, be able to produce an important and influential medical classic.

When the medical profession increases in wisdom, as much time and thought will be devoted to the influence of heredity and environment upon the sick public as is now spent in vainly seeking therapeutic panaceas for chronic degenerative diseases.

Another curious and unfortunate anomaly in undergraduate medical instruction is the paucity of, officially provided, opportunity and encouragement for systematically investigating normal individuals under varying conditions of rest and exercise and under circumstances of emotional and physical stress.

Each medical student would do well to take advantage of every opportunity for making a painstaking and thorough survey of both the physical and psychic state of normal individuals.

Students, both undergraduate and graduate and, unfortunately, practicing physicians as well, are all too likely to consider a thorough survey of a normal individual an uninteresting and profitless procedure.

Such an examination, systematically and thoroughly performed, is, in reality, a most helpful, valuable and educational discipline.

There exists a prevalent impression, both in lay and medical circles, that the profession of medicine can be greatly improved and rendered more "scientific" if physicians limit their professional interests to one organ or to a closely related group of organs. This attitude of mind has resulted in a particularly unfortunate psychologic aspect of modern medicine.

When well educated and thoroughly trained physicians begin to doubt their ability to properly diagnose and treat the common disorders of the most vital organs of the body it is a matter for deep concern.

Since the World War one has had occasion to note the gradual acquisition by many excellent and even superior general practitioners of an entirely unwarranted and unmerited sense of professional inferiority and inadequacy in connection with their ability to worthily serve the best interests of their patients.

Contrasting unfavorably with this unhappy, soul-searching mental attitude of the earnest, conscientious family physician there have been, at times, opportunities for observing an equally unfortunate and unwarranted assumption of professional superiority by inexperienced physicians who possessed limited professional vision and whose assumed superiority was, all too often, based solely upon the restriction of the individual's professional interests to a single organ.

The lay public is not in a position to wisely judge medical matters and one finds that public opinion mistakingly supports the view that a long list of "specialists" are a necessity in modern medicine.

If, on the other hand, one obtained the carefully weighed opinion of the majority of experienced physicians upon this subject it would be learned that, in their judgment, the most generally helpful physician is the well educated, carefully trained, conscientious general practitioner.

There is no activity in medicine in which a well prepared physician can be more generally useful than in general practice nor is there equal opportunity in any other medical field in which there is less spirited competition in performing, each day, superior medical work.

The excellent general practitioner, properly educated and thoroughly trained, is, in reality, a superior and greatly needed specialist in a very broad and inclusive professional field.

When the intelligent lay public awakens to a sense of relative values and becomes willing to properly support in appreciation, and in suitable remuneration, the best type of family physician the medical profession will be in a much more equable economic situation and this will be in the interest of all that is best in medicine.

If a physician desires to become a skilled specialist there is no better preparation than is to be found in the general practice of medicine. The illuminating experience to be gained and profited by as a general practitioner loses nothing of its intrinsic value when added to the training and technical experience of the especially trained worker in a more limited field.

There are surgeons who are excellent operators whose professional judgment would have been materially improved by the educational advantages of a period of experience in general practice and the physician who enters a specialty without experience in the common disorders of everyday medicine, must overcome a serious handicap and, take precautions against acquiring too limited a view of his specialty and, even more important, too limited a view of the ills of his patients.

We believe that for centuries past physicians have had the greatest opportunities for service to their fellowmen. We are convinced that, taking it all in all, physicians have rendered and do render good and efficient services but it is well for all in the medical profession to remind themselves occasionally that they exist, solely and entirely, for the services they are able to render others.

The application of the Golden Rule in our relationship with our patients is a wholesome deterrent for unfair practices.

**The Clinical Demonstration.**—It is pleasant to begin a series of demonstrations of patients who will illustrate the common or garden varieties of cardiovascular disorders. For

the information of newcomers in the class and for the enlightenment of our ever welcome professional visitors it is well to make the statement that this clinic represents conservative, classical methods of investigation and study.

In this arena, and on many occasions, the eloquent clinical teacher, J. Chalmers Da Costa, stated, with the facility for striking and easily remembered phrases that was so characteristically and inimitably his own, "an intuitive diagnosis is, all too frequently, a rapid and sure method of arriving at a wrong conclusion."

Every clinician who has yielded to the temptation of making a diagnosis without the possession of complete and reliable data can vouch for the truth of that great surgical teacher's statement.

We believe, as Dr. Da Costa and all other good clinicians have believed, that correct diagnoses depend upon a carefully ascertained and properly recorded history, a systematically conducted and painstakingly thorough physical examination, an interested survey of the patient's psychical state, plus the often invaluable confirmatory help afforded by carefully conducted laboratory investigations.

It is well to warn undergraduates of the, often entertained, false impression that clinical medicine ever has been learned, or ever can be learned, in a lecture hall or in a clinical amphitheater.

At best we can hope that you who sit upon the benches can obtain helpful hints as to clinical procedures and methods that you will, individually, carry out, gain familiarity with technical terms and expressions and become acquainted, even from a distance, with the symptomatology and physical signs illustrative of disease.

You will perfect your methods of history taking and of performing physical examinations in the small sections of the class assigned to the dispensaries and wards.

It is well to remember, however, that it will take each of you a professional lifetime to perfect your knowledge along those important lines. A selected number of your group will assist at each clinic and, although you will not, at first, enjoy or appreciate this privilege you will learn by experience that appearing in public where you are to feel yourself "the ob-

served of all observers" is an excellent and invaluable discipline to rid you of a feeling of self-consciousness.

A physician, young or old, who is self-conscious and diffident is greatly handicapped in his professional work as well as in his social relations. Those students who are most reluctant to appear in the clinic as student associates will find that this, at first, unpleasant discipline is most helpful for their professional development. We are to be students together for, it is to be remembered, that a physician continues to learn all his life and when he can no longer increase his knowledge he has, as a rule, outlived his professional usefulness.

Before the first patient enters the arena it is well for us to enumerate the essentials for a correct diagnosis.

1. A carefully ascertained history, past and more recent.
2. A systematic and thorough physical examination.
3. The necessary laboratory investigations.

**Case I.**—The first patient we are to study is this genial, smiling, E. H., age thirty-two, white, American of German parentage. He comes before us this morning, not as a sick man, but because he is aware that he possesses what is usually termed, "an interesting heart."

The pertinent details concerning the patient's medical history can be briefly reviewed.

The patient's father died at age thirty-eight of complications incident to, or sequels of, attacks of acute rheumatic fever, namely, organic valvular heart disease. The patient's mother is living and in fair health at seventy-two years of age.

E. H. has no memory of any bed-confining illness until he was twelve years of age when he suffered from an acute febrile ailment that persisted for two months.

The patient states that the family physician termed the disease "rheumatism" although the present memory of the symptoms is confined to repeated attacks of epistaxis, the presence of abdominal aches and pains, much sweating and the presence of headache.

It is only when the patient is carefully questioned that he then remembers that his joints, especially the knees, ankles, shoulders and elbows, were painful and swollen and that he had marked difficulty in moving about in the bed. He remem-

bers, too, that his joints were wrapped in "red" flannel that had been saturated with a liniment possessing the odor of wintergreen.

He recollects, when questioned, that the family physician frequently examined his heart with a stethoscope during this illness and that he was repeatedly warned to take precautions against the tendency to overexercise.

At sixteen years of age, four years after the first attack of rheumatism and without, as far as the patient can remember, any particular exciting cause he was unfortunate enough to have a reoccurrence of the same disorder.

This illness was ushered in by the return of his periods of nosebleeding, much headache and fever and general body aches, accompanied by periods of profuse perspiration but there is no remembrance of joint pains.

The seizure at sixteen years of age is designated by the patient as a "short" attack, lasting but two weeks, as far as bed confinement was concerned, but there is a remembrance of great prostration following the febrile period and prolonged convalescence during which the doctor again warned the patient and his mother of the need for care because of the presence of a heart lesion. The physician at this time advised the patient to plan his life in order to avoid physical overstrain and thus it was that, at an early age, he deliberately selected music as a career.

The third attack of "rheumatism" occurred at age twenty-five, that is twelve years after the first seizure and nine after the second.

This illness at twenty-five years of age was very severe as can be concluded by the period of hospitalization for six months.

During this period the symptoms were frankly arthritic.

The patient remembers the illness all too vividly.

The knees, ankles, wrists and elbows were red, swollen and painful and much attention was devoted to the cardiac region by the attending physician.

Following this third attack of acute rheumatic fever the patient and his mother changed their residence and the son came under our observation and care.

We felt that it would do no harm to have the badly infected tonsils removed and this, in the patient's opinion, has resulted in an improvement in the general health by causing the throat to be less susceptible to infections.

Before us we have a patient thirty-two years of age who has had the misfortune to be afflicted with 3 attacks of rheumatic fever but, fortunately for him, with the exception of those 3 periods of illness the patient has enjoyed what he terms, "moderately good health."

He informs us that as long as he takes matters easily, does not exert himself too much and does not take too much food he continues to feel well.

He has learned by experience two particular hazards.

He cannot, without marked discomfort, use alcoholic beverages and, similarly, he cannot become emotionally disturbed without being made ill by the experience.

The patient states with emphasis that a difference of opinion with anyone upsets his circulation even more than does unusual physical effort. Having heard the medical history there is now an opportunity of examining the man.

We note that the pupils are equal and react normally. The teeth seem free from evidences of gross pathology and the tonsils have been thoroughly removed. There is but one method of making a satisfactory heart and lung examination and this involves the complete removal of the patient's clothing above the waist.

Suitable loose chest covering must be provided both for the protection of the patient from cold and that the patient may feel perfectly comfortable in mind during the examination but, it is to be remembered, that such chest covering should be so arranged that the areas under examination may be completely revealed.

The most difficult feature of the usual chest examination has to do with the removal of the body covering.

Complete and thorough examinations prevent serious mistakes and are, in effect, an efficient therapeutic measure.

As we now glance at the patient he, at first, appears a well-conditioned athlete. His color is excellent, there is no evidence of cyanosis, he is well nourished and appears free from distress.

When we come to study the man more carefully, however, we note that the flesh is flabby and the patient frankly informs us that he finds it most difficult to restrain his appetite to the quantity of food that his ability to exercise requires.

Those near the patient may notice that there is an unusual and abnormal pulsation in the arteries of the neck and, in addition, the veins of this region are prominent from abnormal distention.

It is well to remember that the palpation of an artery invariably reveals a definite pulse while a vein, no matter how large or distended, can never be felt to pulsate.

Those observers who are quite near the patient may readily note that there is a synchronous nodding of the head with each arterial pulsation in the neck. We can safely exclude in this patient's case, the effect of emotional disturbance upon his heart and vessels because he is a veteran of many appearances in this arena and, for the additional reason that, as a musician, he frequently appears before much larger and more critical audiences without pulse disturbance.

It is well to remember that there is but one method of becoming an expert physical diagnostician and this method consists in thoughtfully and painstakingly examining enough human subjects to perfectly familiarize oneself with all variations of human bodies, in health and in disease.

We will now have a student sit before the seated patient and ask him to determine the exact site of the cardiac apex.

This determination is, in my judgment, the most important single feature of any cardiovascular examination.

The student is surprised to note that, in spite of a chest well padded with fat, he is able to both see and easily palpate the apex beat of the heart in the sixth intercostal space at a point not far removed from the anterior axillary line.

The next student is asked to observe the precordial pulsations and to palpate the left border of the heart.

The student remarks that he does not think it probable that the left border of the heart can be felt in such a well nourished subject.

This is, unfortunately, a false impression, not limited to undergraduates. When the student attempts to palpate the border he finds that it can easily be accomplished. The

left border is found displaced well to the left of its normal position.

The next student will, by percussion, exclude the possibility of the heart being displaced by a collection of fluid or air in the right pleural space. Normal resonance is found over the right lung and this tends to exclude both the presence of fluid and of an excess of air, namely, a pneumothorax.

The student who located the apex beat in its displaced position is interested to learn the cause of a palpatory thrill that he felt over the cardiac apex. A vascular thrill has been well described as a palpatory murmur and a vascular murmur may well be considered an auscultatory thrill.

Each thrill and murmur is due to vibrations induced by blood currents but one learns by experience that certain murmurs do not produce perceptible palpable thrills and that certain vascular thrills do not cause demonstrable murmurs.

We will have the student who noted the thrill locate it again and inform us whether its appearance is synchronous with the apex beat of the heart or whether it is felt after the apex beat.

The student states that the thrill at the apex can be definitely felt prior to the apex beat and this indicates that the thrill occurs in the diastolic phase of the ventricles' activity.

A thrill, in this period of ventricular activity, felt at the apex usually indicates an obstruction at the mitral orifice.

We will now have the second examiner palpate the chest area over the base of the heart and the area superior to and between the clavicles.

At the base of the heart and above the clavicles a marked thrill can be felt. We find that the basal thrill occurs with ventricular systole and this is easily estimated by noting that the thrill is synchronous with the carotid pulsation that is so markedly evident.

The student whose hand has been resting over the body of the heart states that there is an additional thrill in this area, not occurring with the carotid pulse.

This thrill is much more evident than the thrill that is palpated at the cardiac apex.

It is obvious that in this patient's heart there are present abnormalities of blood flow that it is necessary for us to study and understand.

Over the apex there is a late diastolic thrill, due to left auricular contraction and we know that, in this area, such a thrill usually indicates an obstruction of the mitral orifice.

The systolic thrill at the base is, obviously, due to an obstructive lesion at the aortic valves for it is easy to palpate a similar systolic thrill in the neck arteries above the obstruction.

The long drawn out diastolic thrill felt over the precordium is due to a regurgitant flow of blood through the aortic valve as the blood abnormally returns from the aorta through an incompetent valve.

It is, in my opinion, most helpful for the examiner to be able to decide from the medical history, from inspection and skilled palpation alone what the probable nature of the cardiac lesion may be before he auscultates the heart. In the examination of this particular patient so exaggerated are the palpatory signs, that one can be confident of the nature of the lesions without the aid of auscultation.

We will now have an examiner listen to the various valve areas and tell us of the auscultatory evidence.

The student describes a loud and long murmur, occurring in ventricular systole at the apex of the heart.

Such a murmur is to be expected in so large a heart even if the valve leaflets were unaffected.

No orifice so stretched by hypertrophy of the left ventricle could be controlled by the normal valves.

The student is disappointed to note that the time of the murmur is not synchronous with the late diastolic thrill that he can feel so easily at the apex.

The student must learn, as every clinician is forced to learn by experience, that one must not be content to listen alone to a very small area about the cardiac apex but he must listen all about the apex of the heart and, especially, above the apex if he is to perfectly interpret the timing of mitral valve orifice murmurs.

The student has now located an area nearly 2 inches above the apex of the heart where it is easy to be sure that one hears two distinct murmurs. One occurs in the period of ventricular systole and one in the period of auricular systole, namely, occurs late in ventricular diastole.

It is interesting to note that the systolic (regurgitant)

murmur produces no palpatory thrill but the obstructive lesion at the mitral valve orifice causes a distinct late diastolic thrill.

When one listens at the aortic cartilage a loud, harsh and prolonged rasping murmur is heard and this sound is transmitted into the vessels of the neck. If one, however, listens to the area over the fourth, left, intercostal space close to the sternum one hears both a long and harsh systolic murmur that is most clearly audible at the aortic cartilage and an equally long but much softer murmur during the entire stage of ventricular diastole.

The murmur heard during ventricular diastole over the body of the heart is so much softer in quality of sound that many students find such a murmur inaudible until their attention is especially directed to the so-termed "silent phase" of diastolic relaxation.

To have the patient exhale and then, for a few seconds, stop breathing will, by exclusion of breath sounds, cause the heart murmurs to be much more evident.
